Foreword

Confronted by competitive pressures and the worst economic climate in decades, today's enterprises need to be increasingly focused on leveraging SOA and BPM to meet their business objectives and capitalize on market opportunities. With mashups and Web 2.0 capabilities becoming ever more prevalent, SOA has reached a level of pervasiveness that requires businesses to quickly adapt. Nowhere is the need more evident than with the millions of mobile workers who toil each day outside the bounds of the traditional enterprise. These workers depend on their devices to consume services and enable business processes cleanly and efficiently while being flexible enough to integrate behavior and business logic changes without requiring new deployments; they expect changes in backend enterprise systems to be totally opaque.

Approaches that increase flexibility help limit the impact on the consuming side when changes are made on the provider side, which leads to greater business value, better development practices, and faster time to market. Dexterra is leading enterprise mobility by example. At Dexterra, we embrace service-orientation in building composite mobile solutions that deliver SOA and BPM best practices to help demanding companies automate previously manual processes, empower employees with the information they need to improve job performance, and transform the enterprise with real-time visibility and control. Our Dexterra Concert mobile platform embodies this SOA approach to enable enterprises to drive dramatic improvements in productivity, performance, flexibility, and responsiveness.

Marc Fiammante is a proven authority on the topic of SOA, having spent years leading field projects and delivering SOA and BPM adaptability. The insights he has accumulated in this book make it an extremely useful asset and reference point for enterprises looking to implement or gain greater value from their SOA and BPM strategy and to extend the capability to workers of all types, mobile or not.

—**Michael S. Liebow**
CEO, Dexterra

From Simplified Integration to Dynamic Processes

He that will not apply new remedies must expect new evils; for time is the greatest innovator.

Francis Bacon

Common Pitfalls Limiting the Value of SOA and BPM

When Services Oriented Architecture (SOA) was initiated, the simplified integration capabilities brought hopes of a simplified business and IT landscape with reusable business components enabled by open technologies. A few years later, the results are uneven; some have experienced substantial benefits from a move to SOA, while others experienced more average value, even though they've used the appropriate technologies.

There are multiple reasons for not realizing the full business value of this services approach. Let's look at three essential reasons:

- **Many projects simply use advanced technologies to implement a client/server approach on Web Services**—Even though the protocol and technical adaptation is no longer a problem, they faced the same issues as a decade ago: changes to the server interfaces leading to client changes. My team faced such a scenario when a large bank decided to expose all its mainframe transactions as Web Services, but the operation semantic remained the same as for mainframe transactions. This pure bottom-up approach did not bring much business value, and in some cases, it led to worse performance.
- **Business processes reintroduce the tight coupling of flexible business services**—In many cases, Business Process Management (BPM) has been established as a disconnect approach from the SOA approach in which business services were limited to the exposure

of existing application functions. This model fails to address the modularization and variability of the business processes, and the processes act like glue rigidifying the services. For example, a large telecommunications operator implemented an end-to-end order management in a very large, single Business Process Execution Language (BPEL), including more than 300 activities, and ultimately faced a lack of reusability when some sequences could have been modularized and exposed as services.

- **Rigid information models are used to expose business services**—In many cases, services are only viewed as operations, forgetting that the business information structure they carry will vary as well with the evolution of the business. For example, another telecommunication operator was updating its product catalog weekly and generating a new schema at each change. This led to instability of the exposed services and integration processes, and delayed IT projects rather than enabling faster cycles.

Each of these experiences induced a deeper thinking process. What should be the essence of a business variable approach? How can we reach a true business/IT alignment with the expected shortened IT cycle enabling faster and cheaper business reactions?

How Other Industries Approach Varying Conditions

The IT industry is not the first industry to face varying conditions. Even though computing technology itself has had some approaches to variability in the past, such as overloading or rules engines, here we expose some solutions for which we can find an implementation analogy in the IT industry.

Whether it is in the automotive industry with shock absorbers and suspension, or the building industry with expansion joints, or the mechanical industry with washers, a mediation layer always absorbs the variations of one part without affecting the other part. In these industries, the integrated elements may not need to vary or move internally, but at the end, a dynamic assembly is realized with tightly coupled parts flexibly linked with other parts. Components can be subassemblies with their own internal variability using similar technologies, but the higher level assembler only cares about the external characteristics of the components. Similarly, in the IT approach, there must be a notion of the levels of assembly and the granularity of components.

In all industries, the final assembly is designed based on a global architecture that looks at requirements, operating conditions, and desired capabilities. Dynamicity is not a goal by itself; it has to respond to a specific context and desired states. Take for instance, buildings in Tokyo, which require more flexibility to withstand earthquakes than buildings in Paris. A 4x4 car has to absorb more landscape variations than a limo. Similarly, the enterprise and business architects must look at how the enterprise business model needs to evolve and what market conditions it will face to understand the variability necessary.

A bank we worked with had to implement higher controls on its loan origination processes because of the Sarbanes-Oxley requirements. However, this bank operates in four different countries with four different legislations and four different IT systems. In addition, this bank plans to expand to Eastern Europe in the future. This specific case led to a common process trunk with

variable subprocesses handling specific legislative constraints and a common top-down but variable services definition for account, products, customer information, and so on.

A Streamlined Enterprise Architecture for BPM and SOA

Every industry creates plans to address new markets, customers, or products. Similarly, such a business plan is required for an IT-enabled industry to identify potential evolutions and targeted domain boundaries. Such planning is essential to define which of the components will be tightly coupled as well as where and to what extent flexibility is necessary.

Merging the business strategy, implementation, information, and infrastructure aspects in a single enterprise architecture map is a common pitfall. Good architecture involves separation of concerns. Wikipedia provides a good definition of enterprise architecture that clearly separates the concerns:

The architecture process addresses documenting and understanding the discrete enterprise structural components, typically within the following four categories: Business, Applications, Information, and Technology.¹

In a dynamic enterprise approach using BPM and SOA, each domain requires a specific mapping and domain decomposition leading to a four-layer view of the enterprise with a simple mean to remember them.

There are recognized enterprise architecture frameworks or metamodels in the industry, such as The Open Group Architecture Framework (TOGAF)² and the Zachman Framework.³ TOGAF is a method that addresses reification of the enterprise architecture (A to H) and the “why” (requirements), but does not separate as clearly as the Zachman Framework the “what,” “how,” “where,” “who,” and “when.” The business information domain is covered by the “what,” the business logic and functions performed are described by the “how,” the various locations and topologies where the enterprise performs business are analyzed in the “where,” the enterprise organization and the various actors are formalized in the “who,” the events and dynamics of the business flows are modeled in the “when,” and finally, the enterprise goals and requirement are captured in the “why.”

However, a fully fledged enterprise architecture with an exhaustive approach for each of the preceding layers is perceived as a costly and lengthy process that does not always provide quick wins and pragmatic results. Applying these methods and frameworks to their full extent for an enterprise can be important; however, in a dynamic BPM and SOA approach, we need to apply a streamlined approach that is affordable and still has the necessary architectural models and work products.

The four domains—Business, Applications, Information, and Technology—are particularly important to an SOA and BPM approach as business processes consume business services exposed from applications or other business process modules. These business services apply functions on core business entities and information that allow their flexible integration at the enterprise level. The applications also consume technical services from the infrastructure layer. *Technical services* refer to services that do not pertain to a particular business domain but are common technical functions made available by the IT to the application layer. Examples of these

subsequent chapters of this book. In this chapter, we look at bridging the enterprise architecture with this business modularization.

It is essential to identify the business components that deliver business capabilities and act as service centers in the enterprise that have the potential to operate independently. These components deliver value to the enterprise through their ability to deliver a unique set of business capabilities.

The need to operate independently necessitates that a business component be at the intersection of several axes, which could potentially include

- A business area or a decomposition of a business area
- An organizational structure operating within a business area
- An accountability level
- Business life cycle phases

Based on these different views, there are several approaches for defining a business map, the business components, and the business model. However, they all provide a decomposition of the business of an enterprise. A business process map is the static landscape on which business processes and business events provide dynamic behavior. A few standards are available, and in the next sections, we walk through some public examples of such enterprise maps and decompositions.

NGOSS Business Process Framework (eTOM)⁴

The enhanced Telecom Operations Map (eTOM) from the New Generation Operations Systems and Software (NGOSS) standard provides a business process functional decomposition framework for telecommunication service providers and serves as a neutral reference point and blueprint for decomposing processes to a level 3 of a functional decomposition tree. In Figure 1-2, you have a first level of decomposition with the verticals such as Fulfillment and an orthogonal first level of decomposition, Customer Relationship Management. At their intersection, there will be further decomposition in level 2 process catalogs such as Order Handling, which itself contains a further decomposition into a level 3 modularization.

This top-level map is complemented with a level 3 functional decomposition in the 300+ paged GB921D document, “The Business Process Framework (eTOM).”

Even though the standard says in business process decomposition no workflows are standardized, only a static functional decomposition of the business operations is provided. This is a good starting point, but the telecommunications business is highly dynamic, and static workflows are necessary for the modularization but insufficient for real business operations.

APQC Process Classification Framework⁵

The APQC (American Productivity and Quality Center, although now worldwide) is a standards body developed a classification of enterprise most common processes and captured that classification as a common language and open standard.

Particularly the classification looks at decomposition of the enterprise into finer grained elements and creating a tree of four levels, where each level addresses a particular semantic of the enterprise business (see Figure 1-3).

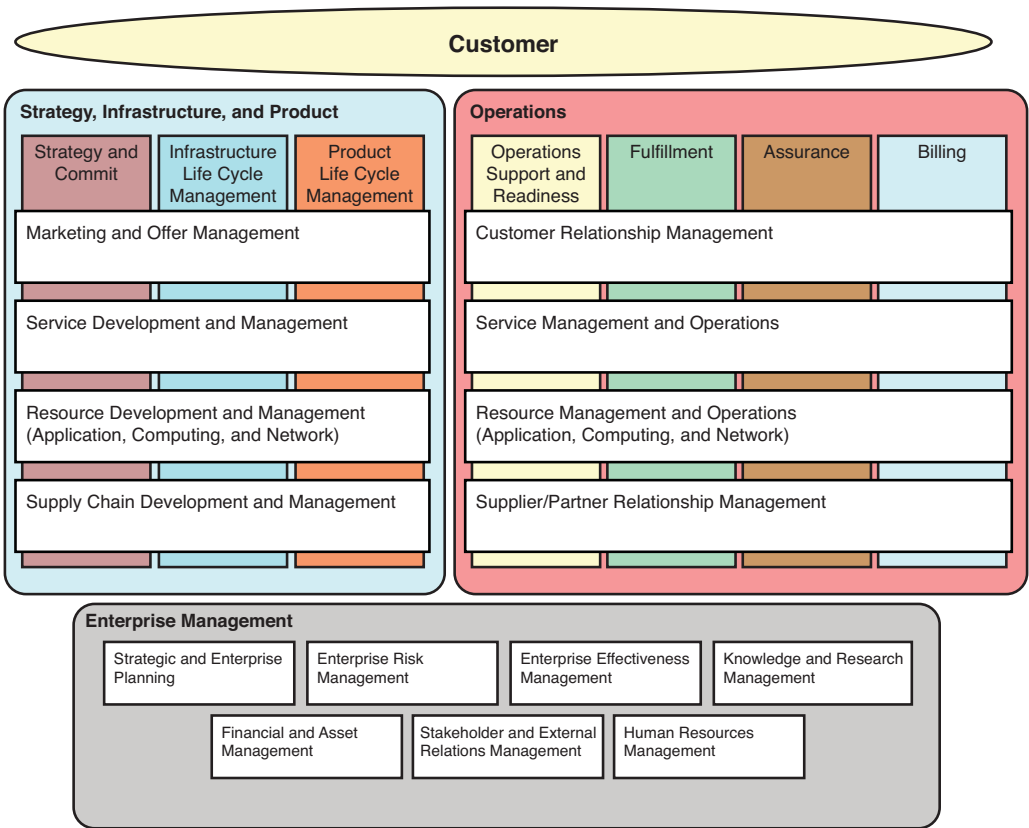

Figure 1-2 The Enhanced Telecom Operations Map (eTOM)

The Process Classification Framework (PCF) includes process groups and more than 1,500 processes and associated activities down to a level 4 of decomposition.

An essential aspect of the PCF is that it provides a standard for naming the different levels, which interestingly enough can be matched with the three eTOM levels. Similarly, even though the level 4 activities are usually sequential, there is no workflow standardization in the PCF.

These four levels are

1. **Categories**—Classifying business competency domains of the enterprise
2. **Process Group**—Grouping processes in business components that apply to similar business entities
3. **Process**—Formalized list of tasks and activities required to achieve a specific aspect of a business component
4. **Activity**—The granular business definition of an element that is chained by a higher level process.

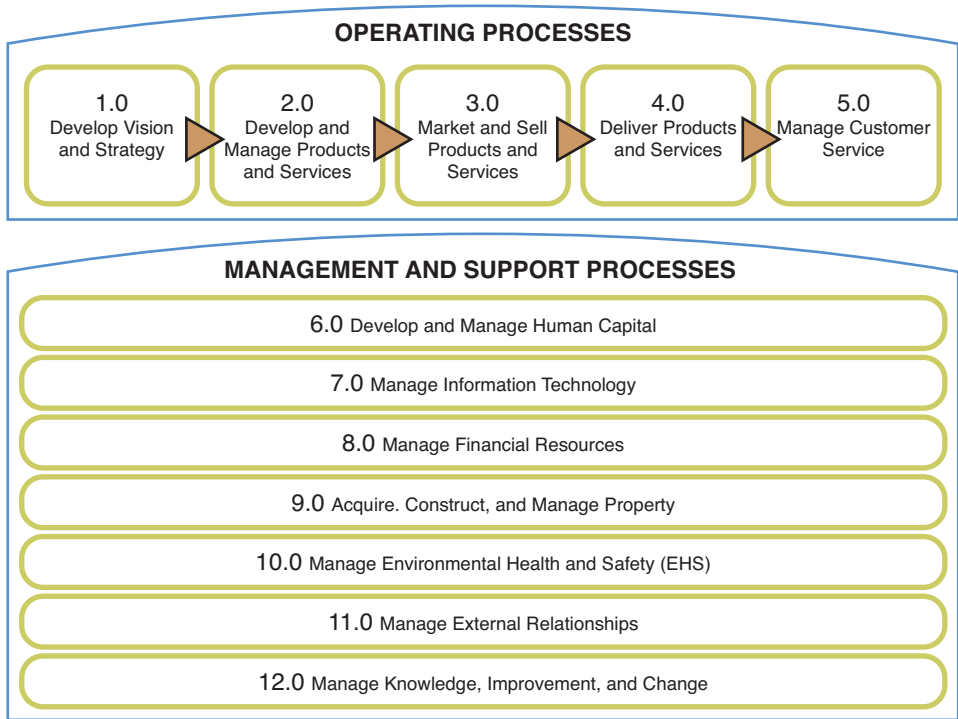

Figure 1-3 The PCF organizes processes into 12 enterprise-level categories.

This classification serves as the basis for further discussions in this book, particularly in the business service granularity discussion.

IBM®’s Component Business Modeling⁶

This approach from IBM is a new way of looking at an enterprise business. The Component Business Modeling (CBM) methodology identifies the basic building blocks of an enterprise business, as shown in Figure 1-4, to help address the future challenges of the enterprise.

This map is a mean to identify business components and create a business strategy for the enterprise. These business components have functionality that occurs once within the enterprise, and they act as business service centers that have the potential to operate independently. This enables the replacement of one business component by another implementation. For example, the product fulfillment can be delivered by many factories around the world, but the enterprise expects the same services from all product fulfillment instantiations around the globe. In one country or for one given product, the enterprise can own the factory while in another country, it can be a contractor. However, each business component delivers value to the enterprise through its ability to deliver a unique set of common services per business component function.

| | | | | | | |
|---------|-------------------------|--------------------------|-------------------------|---------------------|----------------------|----------------------------------|
| | Business administration | New business development | Relationship management | Servicing and sales | Product fulfillment | Financial control and accounting |
| Direct | Business planning | Sector planning | Account planning | Sales planning | Fulfillment planning | Portfolio planning |
| Control | Business unit tracking | Sector management | Relationship management | Sales management | Fulfillment planning | Compliance reconciliation |
| | Staff appraisals | Product management | Credit assessment | | | |
| Execute | Staff administration | Product delivery | Credit administration | Sales | Product fulfillment | Customer accounts |
| | Product administration | Marketing campaigns | | Customer dialog | Document management | General ledger |
| | | | | Contact routing | | |

Figure 1-4 CBM map showing basic business building blocks

The implication is that explicit processes operate within the boundaries of a business component and use other business components’ services to chain into the realization of processes that span the enterprise.

The granularity of business components is, however, often too high. In a dynamic process approach, these maps serve as the basis for further functional decomposition, and they can be considered as level 1 and level 2 of the APQC Process Classification Framework.

SCOR—The Supply-Chain Council

The Supply-Chain Council is a nonprofit global independent organization, composed of many companies around the world, which has produced the Supply-Chain Operations Reference (SCOR) model. This model is a process reference model that integrates the best practices for supply-chain operations business process reengineering.

SCOR addresses five distinct business domains called **management processes**, which are plan, source, make, deliver, and return.

In addition, the Council defines four levels of decomposition but only addresses the first three levels in the standard. The fourth level is the business differentiator of each company.

These four levels are

1. **Process Type**—This level 1 or top level provides a balanced cross business domains and cross process categorization. It defines the scope and content of the previously mentioned management processes.
2. **Process Category**—This level 2 or configuration level provides a reconfigurable level that companies will adjust to their own business plans.

3. **Process Element**—This level 3 or process element level contains the process modules that operate within a business component and can be reconfigured to achieve the higher level processes.
4. **Activities**—This level 4 or implementation level contains the necessary tasks and granular business services. SCOR standard considers this level to be specific to each and every enterprise and does not standardize this level.

Process model decomposition appears as a common practice among the publicly available models and standards. They do not all use the exact same terminology, but they all tend to modularize the representation of the business as a hierarchy and sequences of lower sets of business tasks.

As a confirmation that tree decompositions can be applied to process decomposition let me quote “A Coordination-Theoretic Approach to Understanding Process Differences” from MIT Sloan School of Management to show that derivation trees are common ways of designing processes for modularity and reusability:

By applying top-down coordination-theoretic modeling, supported by a handbook of generic coordination mechanisms and exceptions handlers, we were able to create derivation trees for all three processes that made the source of their similarities and differences much easier to identify.⁷

Usually significant variations appear below the third level of decomposition in being consistent with APQC at the task level defined by its categorization.

Defining Service Granularity from Business Maps

My customers frequently ask, “What is a good service granularity?” Business maps and decompositions are a particularly powerful tool to identify a service granularity and, thus, answer this question. I regularly use them in customer meetings and receive excellent feedback.

However, to answer this question, first we need to precisely define a service. In the following discussion and throughout this book, we use these definitions:

- **Business service**—The grouping of repeatable business tasks that address the same functional domain, for example, Process Customer Order. Business policies are defined at this business service level, such as policies to handle various business services for corporate customers or individuals. The term we use is specifically looking at software components that deliver business logic and not business activities at the level of “sell cars” or “provide mobile telephone services.”
- **Web Service**—A technical representation of the elements of a business service, grouping discrete business tasks together for technical management such as versioning in a technical descriptor using either Web Services Description Language (WSDL) or in a more abstract fashion Service Component Architecture (SCA) as technical standards. Looking at the Process Customer Order business service, the included Web Services might be Customer Order Life Cycle Management and Customer Order Information Management. There can be one or more Web Services per business service, but in many cases there will be only one.

- **Service operation**—A repeatable business task. In the previous case, a service operation might be Perform Order Feasibility Check, Submit Customer Order, or Receive Order Status Update. These are usually qualified as operations in the WSDLs or SCA descriptors. The number of operations range from one to ten or more. Given these definitions, let's do a simple computation. At a level 2, an enterprise usually has between 50 to 100 business components or process groups. Down one level, there are between 300 and 1,000 processes in the enterprise. For example, the eTOM telecommunication business process decomposition gives around 400 processes at level 3.

At level 4, the number of tasks will be between 1,000 and 10,000. APQC has 1,500 activities defined at level 4, and if we pushed eTOM to a further decomposition, at a level 4 we have around five to seven times 400, or 2,500 tasks.

We see that this is already a very large number of tasks, and a large portion of these tasks can potentially become business services. If we compute the number of operations, this gives us a potential of 5,000 to 20,000 service operations for the enterprise, a huge effort to manage. However, only a fraction of the enterprise has value to be exposed as business services and processes, and from our experience between 1% and 5% of the potential services operation has reusability value at the enterprise line of business levels.

The conclusions on granularity are

1. A good business service granularity, to maintain value and manageability, is between level 3 and level 4 of the enterprise functional decomposition. This usually corresponds to the APQC level 4, Activities.
2. Without a functional decomposition, there is no way to know the granularity level of a given service.
3. Processes should be modularized using a functional decomposition to make the modules reusable as business services at level 3. At level 4 or under, the business services are exposed from applications as detailed in the section, "Mapping the Enterprise Applications," later in the chapter.
4. Any too fine-grained Application Programming Interface (API) at level 5 or below should be aggregated into a coarser grained service by applying variability on the interfaces and resolving the variability between the façade and the API.

Mapping the Enterprise Applications

There is a difference between the business components and the implementation of the services that they require. Let's look at a concrete example.

At level 3 eTOM defines a Track and Manage Order Handling process, part of the Order Handling group. However this process requires accessing services from a Customer Information Management, a Product Catalog Management, a Billing Management, and a Customer Order Life Cycle Management application, which is implementing the services.

If the intention is to look at a future state architecture, the **ideal application map** must be defined. This is the map that an enterprise would create if there were no financial, time, or technology restrictions. These maps are often delivered by IT consulting companies and often referred to as “city planning.” This application map is the superstructure of interfaces that will be exposed as the reusable business services layer.

Defining these maps in a top-down approach is essential to isolate the business processes that consume services from the real implementations in the existing applications. This top-down approach needs to be complemented by a bottom-up approach that defines how existing or new applications and packages will be adapted to expose these interfaces in a flexible and consistent manner. The best practices for delivering such adaptations are discussed in later chapters of this book.

One standards body standardizes this application map, and it’s no surprise the TeleManagement Forum (TmForum) is the most advanced in that space, as telecommunication operators are faced with exponential growth and dynamic market evolutions, requiring higher levels of standardization for lowering costs.

TmForum Telecom Applications Map⁸

The Telecom Applications Map provides the bridge between the NGOSS standardized business process and information framework building blocks (eTOM and the SID, Shared Information and Data model) and real, deployable, potentially procurable applications by grouping together process functions and information data into recognized operation support and business support applications or services.

Even though no standard can ever represent a perfect systems infrastructure for an operator, the map provided in Figure 1-5 presents a functional and information guideline for implementing a layer of reusable business services exposed by application.

Mapping the Enterprise IT Infrastructure

The business processes and applications require an IT and middleware infrastructure to operate. It is important that this infrastructure also provides support for variability and flexibility at a core technical level. Even though some standards like the Open Grid Services Infrastructure (OGSI)⁹ are looking at standardizing services exposed from infrastructure components, there are no commonly accepted standards for middleware and operating systems services.

One approach to a product-agnostic map is the SOA Reference Model that IBM provides. This model, shown in Figure 1-6, serves as a reference point to position both middleware and functionality within a service-oriented architecture. For further details, see “IBM SOA Foundation: An Architectural Introduction and Overview.”¹⁰

Mapping the Enterprise Information

Information is the essential “logical” asset that links together all layers of the enterprise. As processes do not run in vacuum but carry, transform, and refer to information, the structure of that

information reflects the way the enterprise wants to operate. Figure 1-7 shows how telecommunication operators relate business domains to core entity domains.

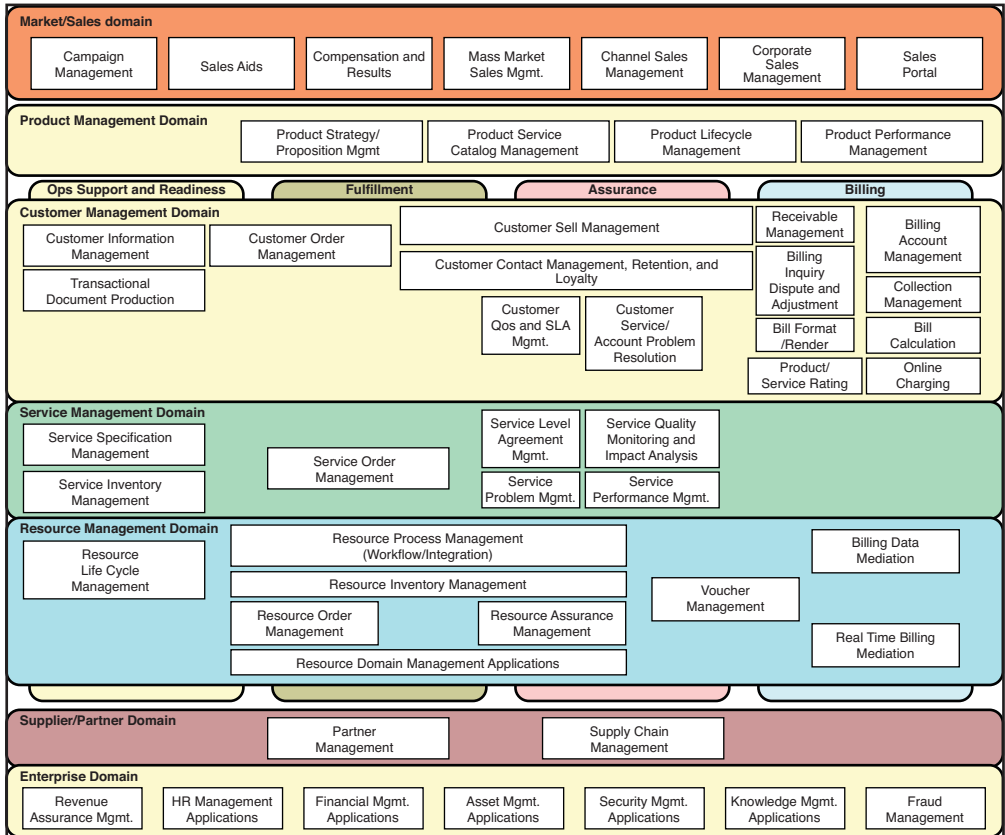

Figure 1-5 The TmForum Telecommunication Application Map GB929 R2.1

The business information model, domain maps, and core entities represent the business view of the information as opposed to data models, which address the technical implementation of managed objects data (see IETF RFC 3444¹¹).

As an example of the influence of business on the information model, let’s look at a retailer that used to sell single products and now wants to sell bundles. Should the bundle business object be considered a product with its own pricing superseding included products, or should it be another type of business entity with a global pricing deduced by applying discounts to the products included in the bundle? This is typically a business question that relies on the business model and needs to be reflected in the information model.

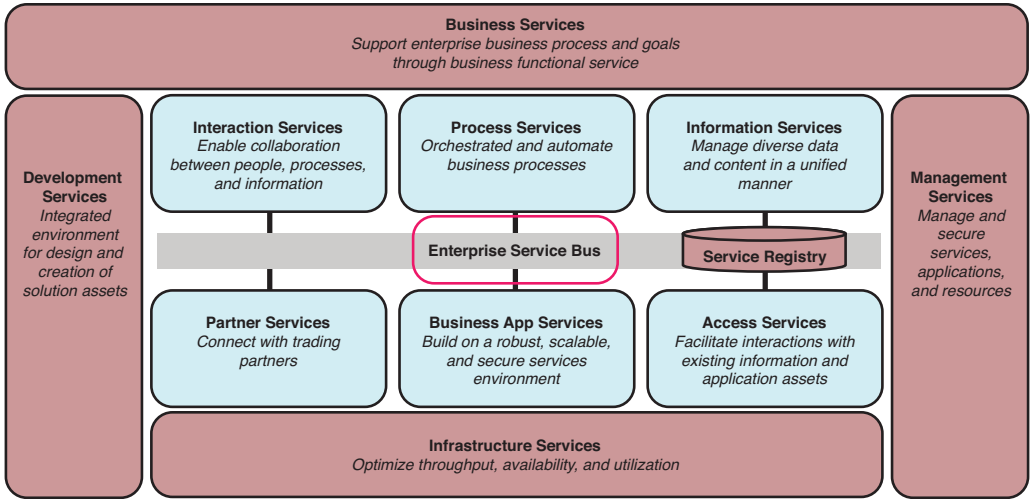

Figure 1-6 The IBM SOA Foundation Reference Model

Figure 1-7 TeleManagement Forum eTOM and SID relationships

The Unified Modeling Language (UML) diagram in Figure 1-8 shows inheritance on the left or none on the right, a consequence of the way the enterprise intends to address markets.

A question arises: Can we make the model flexible enough to address both cases and allow variations of the business model in the future? We address approaches to a realization of this variability in Chapter 3, “Implementing Dynamic Enterprise Information.”

Figure 1-8 Business model affecting the information model

Basic Principles for Enterprise Dynamicity

Now that we have set the static scene for the enterprise architecture, how do we use all these elements in a way that allows a dynamic business and IT approach? Dynamicity implies flows and movements, with events and messages propagating through the enterprise and variations between and within the business components. Flows, such as the Order to Bill, flow across enterprise components and are often referred to as **end-to-end processes**. However, it is essential to differentiate the apparent effect of an event's chain reaction from an explicit choreography of business services owned by a specific organization within the enterprise. Both are called business processes but are different in nature and implementation.

To differentiate these business processes, we use business decompositions and map to a common terminology with a precise definition of the different types of processes at each level. For this purpose, we use the categorization of basic types of processes derived from the Business Process Modeling Notation (BPMN) standard.

Categorizing the Processes

The BPMN standard introduces three basic types of submodels within an end-to-end BPMN model:¹²

1. **Collaboration (global) processes**—Business to business between enterprises or organizations
2. **Abstract (public) processes**—Inside an enterprise across business components or internal organizations
3. **Private (internal) business processes**—Within business components

In addition, BPMN introduces the notions of **pools** and **lanes**, which are also helpful in decomposing processes in modules and grains, allowing them to then be articulated in a flexible and dynamic fashion.

Collaboration (Global) Processes

A collaboration process is the description of the interactions between two completely independent business entities. Cross-industry standards, such as ebXML BPSS, RosettaNet, or to some extent, industry-specific standards, such as ACORD, describe such interactions sequences. The

example collaboration process in Figure 1-9 shows a sequence of purchase order processing between two companies.

Figure 1-9 Example collaboration process

Even though there is a formal sequence, there is not an engine between the enterprises orchestrating that sequence. Each company/enterprise is responsible for sequencing its own part within its boundaries. EDI VANs are an early form of these collaboration processes, which are progressively disappearing because they inhibited flexibility.

Abstract (Public) Processes

These processes represent the overall interactions between different internal organizations in the enterprise owning their internal business rules or sequences. Consequently, abstract processes do not have a single business owner and would not be easily manageable if implemented as a single IT construct.

A first, obvious level of abstract processes is between business components as defined previously, but looking at the APQC decomposition, these abstract processes also occur between the processes at level 3 of the Process Classification Framework. Just as for the collaboration processes, there cannot be an engine controlling the interactions between the business components or level 3 processes because there would not be an owner of the logic in that engine. The overall sequence is the result of services calls and events occurring between each of the level 3 processes or business components. Understanding this difference between an explicit control and an implicit realization of the business process is essential to understanding the approach for implementing dynamic business processes.

In Figure 1-10, the “sales to bill” abstract process is represented by the interactions between the business components.

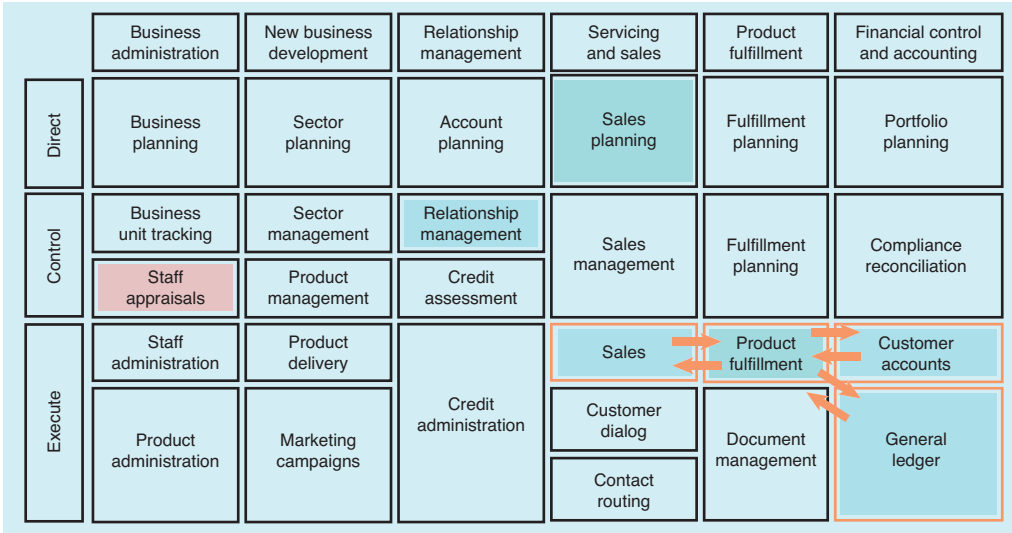

Figure 1-10 Abstract sales to bill process

Private (Internal) Business Processes

Within a single organization with a single identified business owner, the owner can manage the rules and sequences of tasks, which are then private to that “owner” or his delegates.

As a result, private processes are preferable for explicit flow control and automation because they are manageable assets of the enterprise, for which stake holders and life cycle can define.

They can be either explicit, if expressed in a workflow language or service choreography/orchestration language such as XML Process Definition Language (XPDL) or Web Services Business Process Execution Language (BPEL), or implicit, if resulting from the code running inside a particular application or package such as the ones provided by companies like SAP, Oracle, Amdocs, and so on. These processes chain to other private processes either by the means, events, or services calls. If they are exposed as services and consume services, they then can become components in an assembly model, such as standardized by the Service Component Architecture standard from the Open SOA organization.¹³ These private processes match the APQC processes that are at decomposition level 3. They operate within the boundaries of a business component, and there can be several private processes in a given business component or within a finer grained decomposition. Figure 1-11 shows an SCA assembly diagram where the customer order process (ProcessCustomerOrder) is exposed as a service and consumes other services, one of which is another process validating the customer order.

This private process is exposed from within the eTOM level 3 as shown in Figure 1-12.

As you can see the service component in Figure 1-11 has more interfaces than the level 3 of the process decomposition in Figure 1-12, highlighting the difference between a component

providing an implementation in the application map and a private process identified from the process decomposition.

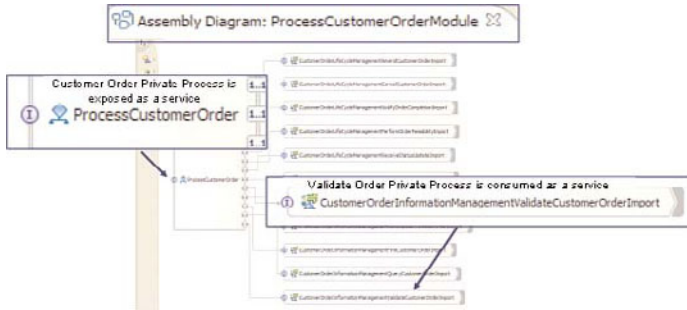

Figure 1-11 Private process exposed as a component and consuming other processes

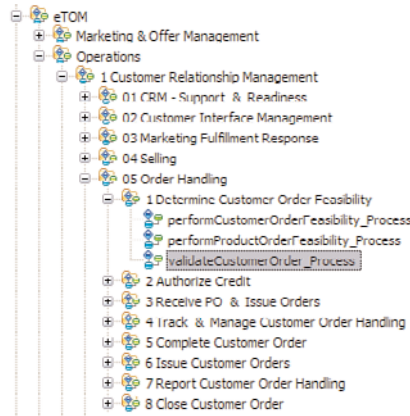

Figure 1-12 Private process in eTOM level 3

Pools/Lanes

Within a private process, a **lane** represents a sequence of tasks or activities driven by a specific participant. A participant can be any specific party role such as a buyer, seller, or call center operator, but also it can be a technical participation such as bus mediation or a program routine. The identification of a lane's nature has an impact on the selection of the appropriate technologies for implementing particular portions, services, or a private process. **Pools** are group of lanes and seem to imply multiple actors. However, this is not explicitly stated in the BPMN standard.

Applying Decomposition to End-to-End Process

As a consequence of decomposing processes in categories, an end-to-end process is the abstract or collaboration process resulting from the assembly of private processes that group the lanes that interact within their boundaries.

Here is an example or “order to cash” end-to-end abstract process for telecommunication operators, composed of a chain of private processes contained within the boundaries of a business component.

In Figure 1-13, we identify variations of private processes, such as the various service configurations and resource provisioning. This example also looks at private processes that are common successors in an abstract flow, such as the Set Top Box configuration required by the three services of a triple play—that is, Internet, television, and voice-over-IP calling services.

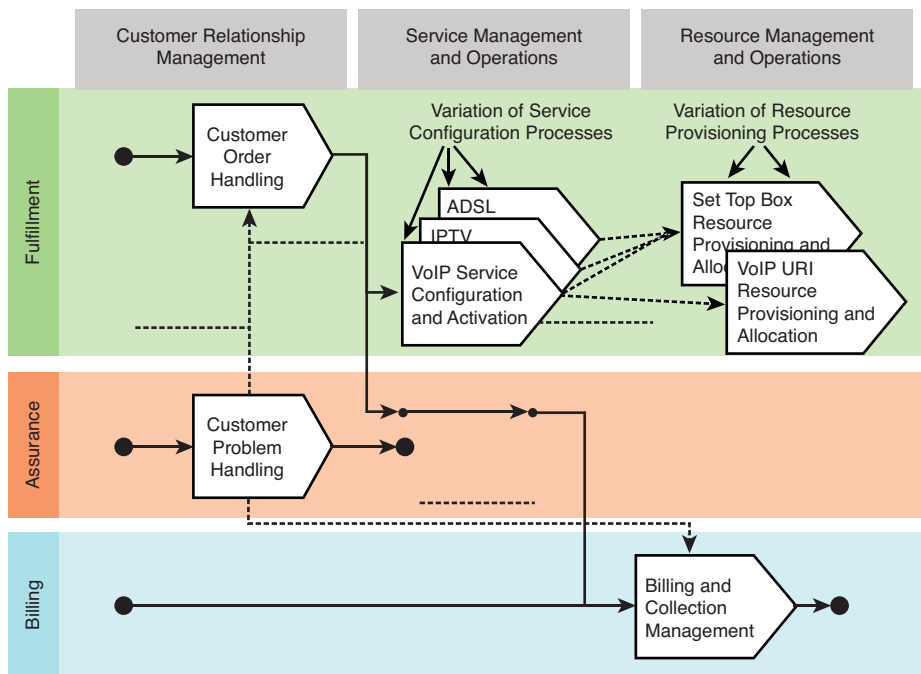

Figure 1-13 Abstract process of chaining private processes on a business map

In this specific case, the services can be submitServiceOrder with three implementations: submitServiceOrderForVoIP, submitServiceOrderForIPTV, and submitServiceOrderForADSL.

In a dynamic process approach, we must be able to add a quadruple play service such as gaming, with its specific service configuration and resources, without having to regenerate and test the “end to end” abstract process. This can only be achieved by means of dynamic binding and coordination between the various private processes.

Impact of Business Information Changes to Processes

The less you carry, the more agile you are. Similarly, the less information processes carry, the more they are able to handle variations of the enterprise information. But that information still needs to

be accessible from the various business organizations of the enterprise, and the appropriate information must be available to the business components that require it for valid business needs.

To reach process agility, we have to move from a processes that carries explicitly all the information to processes that refer to information preserved elsewhere. Then, we only pass the core of the decisional information through processes, and preserve the bulk of the information using a master data management approach and information services to access that data as required by the business components and processes.

This still does not solve the variation of the interface to that information if attributes are added. An enterprise information variability approach is the necessary complement to ensure that within acceptable limits, the information model characteristics can change without affecting the interfaces.

The Enterprise Expansion Joint

This process and information dynamicity requires flexibility, and a mediation layer between components is one of the elements that provides such flexibility. The initial solution to the mediation layer in IT and a services-oriented architecture has been the Enterprise Services Bus. However, these buses often address the technical variability, looking at protocols and messaging, leaving the content interpretation to the integrated consumers or providers.

There is a need to push the mediation layer capabilities to content and business semantic adaptation, thus removing the interface's tight coupling of consumers and providers. As a simple example, the IT solution should enable the evolution of the versions of provided business services without requiring an immediate regeneration of business service consumers.

All the additional capabilities lead to what I call the **enterprise expansion joint**, the capacity for the business to expand using existing IT capabilities, without having to enter a long delivery process. The business variations of this expansion joint have to be bound to precisely identified limits that should be identified during the enterprise architecture phase. The enterprise architecture modeling method must then address the sizing of the business variability that this expansion layer can absorb, looking at foreseeable future business evolutions.

I had a concrete case where an enterprise wanted to deliver a new customer application and process while planning to change billing systems in a later phase. The target was to allow this change of billing systems for another packaged application without affecting any of the elements of the new customer care environment. So, the approach was to define what business services a billing system should expose to customer care in a top-down fashion and then use the mediation layer to perform the adaptation between exposed APIs and desired granularity and variability. In this specific case, the existing billing system was Tuxedo-based and required to use units of work in C for consistency, which led us to create a specific adapter, delivered in less than one month using the available adapter frameworks.

In addition to the granularity adaptation, the mediation layer may also have to address state as the reusable business services are designed to be independent of any implementation. Thus it may not expose specific data that is necessary for a specific application or package realizing the service.

In Chapter 6, “Implementing the Enterprise Expansion Joint,” we discuss a set of techniques for realizing such a layer.

Summary

In this chapter, we saw multiple aspects for an enterprise to address to realize the value of a truly dynamic BPM and SOA approach. This realization requires structuring the business, defining the business goals to identify foreseeable business variation, mapping organizational ownership to process architecture, as well as structuring the business information. There is no “one size fits all” solution; however, a set of modeling steps and implementation techniques are part of an enterprise architecture approach and are discussed in Chapter 2.
