Index ........................................................................ 779
Foreword

I had met Itzik Ben-Gan briefly a couple of times and knew of his reputation, so I was looking forward to his afternoon session on avoiding cursors in SQL programming at PASS. I was lucky to get there early, as the large room filled up quickly. Itzik took a couple of SQL programming problems and diced them up in the most skillful and entertaining way, showing the elegance and efficiency of set-oriented thinking. The audience loved it—and so did I, except I had a different angle. Having worked on the internals of SQL Server, I could see Itzik touch the product nerves in his demos, and I admired how he turned features into beautiful solutions. After the session, I asked one of the attendees what had been his main takeaway, curious about which of the many techniques would have stood out for him. He looked at me, mildly surprised, and just said, “The man is a genius!” That pretty much sums it up.

This question of cursors is more fundamental than it may appear at first. It points to a deep dichotomy of tremendous practical importance. Most of us were taught to program by chopping up a task into smaller steps that, when executed in sequence, perform a desired computation. But if you approach SQL programming this way, you will get only mediocre results. Your code will be much larger and harder to maintain. It will be less efficient, less flexible, and less tunable. Using SQL effectively is not about an incremental extension of your procedural programming skills or about a specific collection of tricks. Writing SQL well requires approaching problems with a different mind-set—one that is declarative and set oriented, not procedural. This is the dichotomy.

*Inside Microsoft SQL Server 2008: T-SQL Querying* puts together all the ingredients you need to understand this declarative and set-oriented way of thinking and become a proficient SQL programmer, thus making an important contribution to the SQL Server development community. Its chapters on formal foundations help you understand the basis for the language philosophy and get a sense for its potential. The language itself is covered thoroughly, from the basic operations to the most advanced features, all of them explained in the context of real problem solving. The many examples show you what good SQL looks like, and they cover common patterns you are likely to find when writing applications. A comprehensive chapter on query tuning explains in detail the factors that impact performance in the system, how to go about identifying issues, and how to address them effectively.

Itzik assembled a strong team of collaborators to write this book. Coming from different backgrounds, all of them share a deep expertise in SQL, a passion for database technology, extensive teaching experience, and a recognized track record of contributions to the SQL Server community. Steve Kass is known for his depth of understanding and clarity of thought. Dejan Sarka contributes an extensive knowledge of the relational model and a breadth of database technologies. As for Lubor Kollar, I’ve had the pleasure of working with him on the definition, design, and implementation of the Query Processing engine of SQL Server for over a decade, and I deeply respect his insight. They make an outstanding team of guides who can help you improve your skills.
SQL is a very powerful language, but I believe only a minority of developers really know how to get the most out of it. Using SQL well can mean code that is 10 times more efficient, more scalable, and more maintainable. *Inside Microsoft SQL Server 2008: T-SQL Querying* tells you how.

César Galindo-Legaria, PhD

Manager of the Query Optimization Team, Microsoft SQL Server
Acknowledgments

Several people contributed to the T-SQL querying and T-SQL programming books, and I’d like to acknowledge their contributions. Some were involved directly in writing or editing the books, while others were involved indirectly by providing advice, support, and inspiration.

To the coauthors of Inside Microsoft SQL Server 2008: T-SQL Querying—Lubor Kollar, Dejan Sarka, and Steve Kass—and to the coauthors of Inside Microsoft SQL Server 2008: T-SQL Programming—Dejan Sarka, Roger Wolter, Greg Low, Ed Katibah, and Isaac Kunen—it is a great honor to work with you. It is simply amazing to see the level of mastery that you have over your areas of expertise, and it is pure joy to read your texts. Thanks for agreeing to be part of this project.

To Lubor, besides directly contributing to the books, you provide support, advice, and friendship and are a great source of inspiration. I always look forward to spending time with you—hiking, drinking, and talking about SQL and other things.

To Dejko, your knowledge of the relational model is admirable. Whenever we spend time together, I learn new things and discover new depths. I like the fact that you don’t take things for granted and don’t follow blindly words of those who are considered experts in the field. You have a healthy mind of your own and see things that very few are capable of seeing. I’d like to thank you for agreeing to contribute texts to the books. I’d also like to thank you for your friendship; I always enjoy spending time with you. We need to do the beer list thing again some time. It’s been almost 10 years!

To the technical editor of the books, Steve Kass, your unique mix of strengths in mathematics, SQL, and English are truly extraordinary. I know that editing both books and also writing your own chapters took their toll. Therefore, I’d like you to know how much I appreciate your work. I know you won’t like my saying this, but it is quite interesting to see a genius at work. It kept reminding me of Domingo Montoya’s work on the sword he prepared for the six-fingered man from William Goldman’s The Princess Bride.

To Umachandar Jayachandran (UC), many thanks for helping out by editing some of the chapters. Your mastery of T-SQL is remarkable, and I’m so glad you could join the project in any capacity. I’d also like to thank Bob Beauchemin for reviewing the chapter on Spatial Data.

To Cesar Galindo-Legaria, I feel honored that you agreed to write the foreword for the T-SQL querying book. The way you and your team designed SQL Server’s optimizer is simply a marvel. I’m constantly trying to figure out and interpret what the optimizer does, and whenever I manage to understand a piece of the puzzle, I find it astonishing what a piece of software is capable of. Your depth of knowledge, your pleasant ways, and your humility are an inspiration.
To the team at Microsoft Press: Ken Jones, the product planner: I appreciate the personal manner in which you handle things and always look forward to Guinness sessions with you. I think that you have an impossible job trying to make everyone happy and keep projects moving, but somehow you still manage to do it.

To Sally Stickney, the development editor, thanks for kicking the project off the ground. I know that the T-SQL querying book was your last project at Microsoft Press before you started your new chosen path in life and am hopeful that it left a good impression on you. I wish you luck and happiness in your new calling.

To Denise Bankaitis, the project editor, you of all people at Microsoft Press probably spent most time working on the books. Thanks for your elegant project management and for making sure things kept flowing. It was a pleasure to work with you.

I’d also like to thank DeAnn Montoya, the project manager for the vendor editorial team, S4Carlisle Publishing Services, and Becka McKay, the copy editor. I know you spent countless hours going over our texts, and I appreciate it a lot.

To Solid Quality Mentors, being part of this amazing company and group of people is by far the best thing that happened to me in my career. It’s as if all I did in my professional life led me to this place where I can fulfill my calling, which is teaching people about SQL. To Fernando Guerrero, Brian Moran, and Douglas McDowell: the company grew and matured because of your efforts, and you have a lot to be proud of. Being part of this company, I feel a part of something meaningful and that I’m among family and friends—among people whom I both respect and trust.

I’d like to thank my friends and colleagues from the company: Ron Talmage, Andrew J. Kelly, Eladio Rincón, Dejan Sarka, Herbert Albert, Fritz Lechnitz, Gianluca Hotz, Erik Veerman, Jay Hackney, Daniel A. Seara, Davide Mauri, Andrea Benedetti, Miguel Egea, Adolfo Wiernik, Javier Loria, Rushabh Mehta, Greg Low, Peter Myers, Randy Dyess, and many others. I’d like to thank Jeanne Reeves for making many of my classes possible and all the back-office team for their support. I’d also like to thank Kathy Blomstrom for managing our writing projects and for your excellent edits.

I’d like to thank the members of the SQL Server development team who are working on T-SQL and its optimization: Michael Wang, Michael Rys, Eric Hanson, Umachandar Jayachandran (UC), Tobias Thernström, Jim Hogg, Isaac Kunen, Krzysztof Kozielczyk, Cesar Galindo-Legaria, Craig Freedman, Conor Cunningham, and many others. For better or worse, what you develop is what we have to work with, and so far the results are outstanding! Still, until we get a full implementation of the OVER clause, you know I won’t stop bothering you. ;-)

I’d like to thank Dubi Lebel and Assaf Fraenkel from Microsoft Israel and also Ami Levin, who helps me run the Israeli SQL Server users group.
To the team at SQL Server Magazine: Megan Bearly, Sheila Molnar, Mary Waterloo, Michele Crockett, Mike Otey, Lavon Peters, and Anne Grubb: Being part of this magazine is a great privilege. Congratulations on the 10th anniversary of the magazine! I can’t believe that 10 years passed so quickly, but that’s what happens when you have fun.

To my fellow SQL Server MVPs: Erland Sommarskog, Alejandro Mesa, Aaron Bertrand, Tibor Karasi, Steve Kass, Dejan Sarka, Roy Harvey, Tony Rogerson, Marcello Poletti (Marc), Paul Randall, Bob Beauchemin, Adam Machanic, Simon Sabin, Tom Moreau, Hugo Kornelis, David Portas, David Guzman, and many others: Your contribution to the SQL Server community is remarkable. Much of what I know today is thanks to our discussions and exchange of ideas.

To my fellow SQL Server MCTs: Tibor Karasi, Chris Randall, Ted Malone, and others: We go a long way back, and I’m glad to see that you’re all still around in the SQL teaching community. We all share the same passion for teaching. Of anyone, you best understand the kind of fulfillment that teaching can bestow.

To my students: Without you, my work would be meaningless. Teaching is what I like to do best, and the purpose of pretty much everything else that I do with SQL—including writing these books—is to support my teaching. Your questions make me do a lot of research, and therefore I owe much of my knowledge to you.

To my parents, Emilia and Gabriel Ben-Gan, and to my siblings, Ina Aviram and Michael Ben-Gan, thanks for your continuous support. The fact that most of us ended up being teachers is probably not by chance, but for me to fulfill my calling, I end up traveling a lot. I miss you all when I’m away, and I always look forward to our family reunions when I’m back.

To Lilach, you’re the one who needs to put up with me all the time and listen to my SQL ideas that you probably couldn’t care less about. It’s brainwashing, you see—at some point you will start asking for more, and before you know it, you will even start reading my books. Not because I will force you but because you will want to, of course. That’s the plan at least. Thanks for giving meaning to what I do and for supporting me through some rough times of writing.
Introduction

This book and its sequel—Inside Microsoft SQL Server 2008: T-SQL Programming—cover advanced T-SQL querying, query tuning, and programming in Microsoft SQL Server 2008. They are designed for experienced programmers and DBAs who need to write and optimize code in SQL Server 2008. For brevity, I’ll refer to the books as T-SQL Querying and T-SQL Programming, or just as these books.

Those who read the SQL Server 2005 edition of the books will find plenty of new materials covering new subjects, new features, and enhancements in SQL Server 2008, plus revisions and new insights about the existing subjects.

These books focus on practical common problems, discussing several approaches to tackle each. You will be introduced to many polished techniques that will enhance your toolbox and coding vocabulary, allowing you to provide efficient solutions in a natural manner.

These books unveil the power of set-based querying and explain why it’s usually superior to procedural programming with cursors and the like. At the same time, they teach you how to identify the few scenarios where cursor-based solutions are superior to set-based ones.

This book—T-SQL Querying—focuses on set-based querying and query tuning, and I recommend that you read it first. The second book—T-SQL Programming—focuses on procedural programming and assumes that you read the first book or have sufficient querying background.

T-SQL Querying starts with five chapters that lay the foundation of logical and physical query processing required to gain the most from the rest of the chapters in both books.

The first chapter covers logical query processing. It describes in detail the logical phases involved in processing queries, the unique aspects of SQL querying, and the special mind-set you need to adopt to program in a relational, set-oriented environment.

The second chapter covers set theory and predicate logic—the strong mathematical foundations upon which the relational model is built. Understanding these foundations will give you better insights into the model and the language. This chapter was written by Steve Kass, who was also the main technical editor of these books. Steve has a unique combination of strengths in mathematics, computer science, SQL, and English that make him the ideal author for this subject.
The third chapter covers the relational model. Understanding the relational model is essential for good database design and helps in writing good code. The chapter defines relations and tuples and operators of relational algebra. Then it shows the relational model from a different perspective called relational calculus. This is more of a business-oriented perspective, as the logical model is described in terms of predicates and propositions. Data integrity is crucial for transactional systems; therefore, the chapter spends time discussing all kinds of constraints. Finally, the chapter introduces normalization—the formal process of improving database design. This chapter was written by Dejan Sarka. Dejan is one of the people with the deepest understanding of the relational model that I know.

The fourth chapter covers query tuning. It introduces a query tuning methodology we developed in our company (Solid Quality Mentors) and have been applying in production systems. The chapter also covers working with indexes and analyzing execution plans. This chapter provides the important background knowledge required for the rest of the chapters in both books, which as a practice discuss working with indexes and analyzing execution plans. These are important aspects of querying and query tuning.

The fifth chapter covers complexity and algorithms and was also written by Steve Kass. This chapter particularly focuses on some of the algorithms used often by the SQL Server engine. It gives attention to considering worst-case behavior as well as average case complexity. By understanding the complexity of algorithms used by the engine, you can anticipate, for example, how the performance of certain queries will degrade when more data is added to the tables involved. Gaining a better understanding of how the engine processes your queries equips you with better tools to tune them.

The chapters that follow delve into advanced querying and query tuning, addressing both logical and physical aspects of your code. These chapters cover the following subjects: subqueries, table expressions, and ranking functions; joins and set operations; aggregating and pivoting data; TOP and APPLY; data modification; querying partitioned tables; and graphs, trees, hierarchies, and recursive queries.

The chapter covering querying partitioned tables was written by Lubor Kollar. Lubor led the development of partitioned tables and indexes when first introduced in the product, and many of the features that we have today are thanks to his efforts. These days Lubor works with customers who have, among other things, large implementations of partitioned tables and indexes as part of his role in the SQL Server Customer Advisory Team (SQL CAT).

Appendix A covers logic puzzles. Here you have a chance to practice logical puzzles to improve your logic skills. SQL querying essentially deals with logic. I find it important to practice pure logic to improve your query problem-solving capabilities. I also find these puzzles fun and challenging, and you can practice them with the entire family. These puzzles
are a compilation of the logic puzzles that I covered in my T-SQL column in *SQL Server Magazine*. I'd like to thank *SQL Server Magazine* for allowing me to share these puzzles with the book's readers.

The second book—*T-SQL Programming*—focuses on programmatic T-SQL constructs and expands its coverage to treatment of XML and XQuery and the CLR integration. The book's chapters cover the following subjects: views; user-defined functions; stored procedures; triggers; transactions and concurrency; exception handling; temporary tables and table variables; cursors; dynamic SQL; working with date and time; CLR user-defined types; temporal support in the relational model; XML and XQuery (including coverage of open schema); spatial data; change data capture, change tracking, and auditing; and Service Broker.

The chapters covering CLR user-defined types, temporal support in the relational model, and XML and XQuery were written by Dejan Sarka. As I mentioned, Dejan is extremely knowledgeable in the relational model and has very interesting insights into the model itself and the way the constructs that he covers in his chapters fit in the model when used sensibly.

The chapter about spatial data was written by Ed Katibah and Isaac Kunen. Ed and Isaac are with the SQL Server development team and led the efforts to implement spatial data support in SQL Server 2008. It is a great privilege to have this chapter written by the designers of the feature. Spatial data support is new to SQL Server 2008 and brings new data types, methods, and indices. This chapter is not intended as an exhaustive treatise on spatial data or as an encyclopedia of every spatial method that SQL Server now supports. Instead, this chapter will introduce core spatial concepts and provide the reader with key programming constructs necessary to successfully navigate this new feature to SQL Server.

The chapter about change data capture, change tracking, and auditing was written by Greg Low. Greg is a SQL Server MVP and the managing director of SolidQ Australia. Greg has many years of experience working with SQL Server—teaching, speaking, and writing about it—and is highly regarded in the SQL Server community. The technologies that are the focus of this chapter track access and changes to data and are new in SQL Server 2008. At first glance, these technologies can appear to be either overlapping or contradictory, and the best-use cases for each might be far from obvious. This chapter explores each technology, discusses the capabilities and limitations of each, and explains how each is intended to be used.

The last chapter, which covers Service Broker (SSB), was written by Roger Wolter. Roger is the program manager with the SQL Server development team and led the initial efforts to introduce SSB in SQL Server. Again, there's nothing like having the designer of a component explain it in his own words. The “sleeper” feature of SQL Server 2005 is now in production in
a wide variety of applications. This chapter covers the architecture of SSB and how to use SSB to build a variety of reliable asynchronous database applications. The SQL 2008 edition adds coverage of the new features added to SSB for the SQL Server 2008 release and includes lessons learned and best practices from SSB applications deployed since the SQL Server 2005 release. The major new features are Queue Priorities, External Activation, and a new SSB troubleshooting application that incorporates lessons the SSB team learned from customers who have already deployed applications.

Hardware and Software Requirements

Companion Content and Sample Database

These books feature a companion Web site that makes available to you all the code used in the books, the errata, additional resources, and more. The companion Web site is http://www.insidetsql.com.

For each of these books the companion Web site provides a compressed file with the book’s source code, a script file to create the books’ sample database, and additional files that are required to run some of the code samples.

After downloading the source code, run the script file TSQLFundamentals2008.sql to create the sample database InsideTSQLO8, which is used in many of the books’ code samples. The data model of the InsideTSQLO8 database is provided in Figure I-1 for your convenience.
Find Additional Content Online

As new or updated material becomes available that complements your books, it will be posted online on the Microsoft Press Online Windows Server and Client Web site. The type of material you might find includes updates to books content, articles, links to companion content, errata, sample chapters, and more. This Web site is available at http://microsoftpresssrv.libredigital.com/serverclient/ and is updated periodically.
Support for These Books

Every effort has been made to ensure the accuracy of these books and the contents of the companion Web site. As corrections or changes are collected, they will be added to a Microsoft Knowledge Base article.

Microsoft Press provides support for books at the following Web site:

http://www.microsoft.com/learning/support/books

Chapter 8

Aggregating and Pivoting Data

This chapter covers various data-aggregation techniques, including using the OVER clause with aggregate functions, tiebreakers, running aggregates, pivoting, unpivoting, custom aggregations, histograms, grouping factors, and grouping sets.

In my solutions in this chapter, I’ll reuse techniques that I introduced earlier. I’ll also introduce new techniques for you to familiarize yourself with.

Logic will naturally be an integral element in the solutions. Remember that at the heart of every querying problem lies a logical puzzle.

OVER Clause

The OVER clause allows you to request window-based calculations—that is, calculations performed over a whole window of rows. In Chapter 6, “Subqueries, Table Expressions, and Ranking Functions,” I described in detail how you use the OVER clause with analytical ranking functions. Microsoft SQL Server also supports the OVER clause with scalar aggregate functions; however, currently you can provide only the PARTITION BY clause. Future versions of SQL Server will most likely also support the other ANSI elements of aggregate window functions, including the ORDER BY and ROWS clauses.

The purpose of using the OVER clause with scalar aggregates is to calculate, for each row, an aggregate based on a window of values that extends beyond that row—and to do all this without using a GROUP BY clause in the query. In other words, the OVER clause allows you to add aggregate calculations to the results of an ungrouped query. This capability provides an alternative to requesting aggregates with subqueries in case you need to include both base row attributes and aggregates in your results.

Remember that in Chapter 7, “Joins and Set Operations,” I presented a problem in which you were required to calculate two aggregates for each order row: the percentage the row contributed to the total value of all orders and the difference between the row’s order value and the average value over all orders. In my examples I used a table called MyOrderValues that you create and populate by running the following code:

```sql
SET NOCOUNT ON;
USE InsideTSQL2008;

IF OBJECT_ID('dbo.MyOrderValues', 'U') IS NOT NULL
    DROP TABLE dbo.MyOrderValues;
GO
```
SELECT *
INTO dbo.MyOrderValues
FROM Sales.OrderValues;

ALTER TABLE dbo.MyOrderValues
ADD CONSTRAINT PK_MyOrderValues PRIMARY KEY(orderid);

CREATE INDEX idx_val ON dbo.MyOrderValues(val);

I showed the following optimized query in which I used a cross join between the base table and a derived table of aggregates instead of using multiple subqueries:

SELECT orderid, custid, val,
       CAST(val / sumval * 100. AS NUMERIC(5, 2)) AS pct,
       CAST(val - avgval AS NUMERIC(12, 2)) AS diff
FROM dbo.MyOrderValues
CROSS JOIN (SELECT SUM(val) AS sumval, AVG(val) AS avgval
            FROM dbo.MyOrderValues) AS Aggs;

This query produces the following output:

<table>
<thead>
<tr>
<th>orderid</th>
<th>custid</th>
<th>val</th>
<th>pct</th>
<th>diff</th>
</tr>
</thead>
<tbody>
<tr>
<td>10248</td>
<td>85</td>
<td>440.00</td>
<td>0.03</td>
<td>-1085.05</td>
</tr>
<tr>
<td>10249</td>
<td>79</td>
<td>1863.40</td>
<td>0.15</td>
<td>338.35</td>
</tr>
<tr>
<td>10250</td>
<td>34</td>
<td>1552.60</td>
<td>0.12</td>
<td>27.55</td>
</tr>
<tr>
<td>10251</td>
<td>84</td>
<td>654.06</td>
<td>0.05</td>
<td>-870.99</td>
</tr>
<tr>
<td>10252</td>
<td>76</td>
<td>3597.90</td>
<td>0.28</td>
<td>2072.85</td>
</tr>
<tr>
<td>10253</td>
<td>34</td>
<td>1444.80</td>
<td>0.11</td>
<td>-80.25</td>
</tr>
<tr>
<td>10254</td>
<td>14</td>
<td>556.62</td>
<td>0.04</td>
<td>-968.43</td>
</tr>
<tr>
<td>10255</td>
<td>68</td>
<td>2490.50</td>
<td>0.20</td>
<td>965.45</td>
</tr>
<tr>
<td>10256</td>
<td>88</td>
<td>517.80</td>
<td>0.04</td>
<td>-1007.25</td>
</tr>
</tbody>
</table>

The motivation for calculating the two aggregates in a single derived table instead of as two separate subqueries stemmed from the fact that each subquery accessed the base table separately, while the derived table calculated the aggregates using a single scan of the data. SQL Server's query optimizer didn't use the fact that the two subqueries aggregated the same data into the same groups.

When you specify multiple aggregates with identical OVER clauses in the same SELECT list, however, the aggregates refer to the same window, as with a derived table, and SQL Server's query optimizer evaluates them all with one scan of the source data. Here's how you use the OVER clause to answer the same request:

SELECT orderid, custid, val,
       CAST(val / SUM(val) OVER() * 100. AS NUMERIC(5, 2)) AS pct,
       CAST(val - AVG(val) OVER() AS NUMERIC(12, 2)) AS diff
FROM dbo.MyOrderValues;
Note In Chapter 6, I described the PARTITION BY clause, which is used with window functions, including aggregate window functions. This clause is optional. When not specified, the aggregate is based on the whole input rather than being calculated per partition.

Here, because I didn’t specify a PARTITION BY clause, the aggregates were calculated based on the whole input. Logically, \( \text{SUM}(\text{val}) \ \text{OVER}() \) is equivalent here to the subquery \( \text{(SELECT SUM(\text{val}) FROM dbo.MyOrderValues)} \). Physically, it’s a different story. As an exercise, you can compare the execution plans of the following two queries, each requesting a different number of aggregates using the same OVER clause:

```
SELECT orderid, custid, val,
   \text{SUM(\text{val}) OVER()} \ AS \ \text{sumval}
FROM dbo.MyOrderValues;

SELECT orderid, custid, val,
   \text{SUM(\text{val}) OVER()} \ AS \ \text{sumval},
   \text{COUNT(\text{val}) OVER()} \ AS \ \text{cntval},
   \text{AVG(\text{val}) OVER()} \ AS \ \text{avgval},
   \text{MIN(\text{val}) OVER()} \ AS \ \text{minval},
   \text{MAX(\text{val}) OVER()} \ AS \ \text{maxval}
FROM dbo.MyOrderValues;
```

You’ll find the two plans nearly identical, with the only difference being that the single Stream Aggregate operator calculates a different number of aggregates. The query costs are identical. On the other hand, compare the execution plans of the following two queries, each requesting a different number of aggregates using subqueries:

```
SELECT orderid, custid, val,
   \text{(SELECT SUM(\text{val}) FROM dbo.MyOrderValues) AS sumval}
FROM dbo.MyOrderValues;

SELECT orderid, custid, val,
   \text{(SELECT SUM(\text{val}) FROM dbo.MyOrderValues) AS sumval},
   \text{(SELECT COUNT(\text{val}) FROM dbo.MyOrderValues) AS cntval},
   \text{(SELECT AVG(\text{val}) FROM dbo.MyOrderValues) AS avgval},
   \text{(SELECT MIN(\text{val}) FROM dbo.MyOrderValues) AS minval},
   \text{(SELECT MAX(\text{val}) FROM dbo.MyOrderValues) AS maxval}
FROM dbo.MyOrderValues;
```

You’ll find that they have different plans, with the latter being more expensive because it rescans the source data for each aggregate.

Another benefit of the OVER clause is that it allows for shorter and simpler code. This is especially apparent when you need to calculate partitioned aggregates. Using OVER, you simply specify a PARTITION BY clause. Using subqueries, you have to correlate the inner query to the outer, making the query longer and more complex.
As an example of using the PARTITION BY clause, the following query calculates the percentage of the order value out of the customer total and the difference from the customer average:

```sql
SELECT orderid, custid, val,
    CAST(val / SUM(val) OVER(PARTITION BY custid) * 100.
        AS NUMERIC(5, 2)) AS pct,
    CAST(val - AVG(val) OVER(PARTITION BY custid) AS NUMERIC(12, 2)) AS diff
FROM dbo.MyOrderValues
ORDER BY custid;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>orderid</th>
<th>custid</th>
<th>val</th>
<th>pct</th>
<th>diff</th>
</tr>
</thead>
<tbody>
<tr>
<td>10643</td>
<td>1</td>
<td>814.50</td>
<td>19.06</td>
<td>102.33</td>
</tr>
<tr>
<td>10692</td>
<td>1</td>
<td>878.00</td>
<td>20.55</td>
<td>165.83</td>
</tr>
<tr>
<td>10702</td>
<td>1</td>
<td>330.00</td>
<td>7.72</td>
<td>-382.17</td>
</tr>
<tr>
<td>10835</td>
<td>1</td>
<td>845.80</td>
<td>19.79</td>
<td>133.63</td>
</tr>
<tr>
<td>10952</td>
<td>1</td>
<td>471.20</td>
<td>11.03</td>
<td>-240.97</td>
</tr>
<tr>
<td>11011</td>
<td>1</td>
<td>933.50</td>
<td>21.85</td>
<td>221.33</td>
</tr>
<tr>
<td>10926</td>
<td>2</td>
<td>514.40</td>
<td>36.67</td>
<td>163.66</td>
</tr>
<tr>
<td>10759</td>
<td>2</td>
<td>320.00</td>
<td>22.81</td>
<td>-30.74</td>
</tr>
<tr>
<td>10625</td>
<td>2</td>
<td>479.75</td>
<td>34.20</td>
<td>129.01</td>
</tr>
<tr>
<td>10308</td>
<td>2</td>
<td>88.80</td>
<td>6.33</td>
<td>-261.94</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In short, the OVER clause allows for more concise and faster-running queries.

When you're done, run the following code for cleanup:

```sql
IF OBJECT_ID('dbo.MyOrderValues', 'U') IS NOT NULL
    DROP TABLE dbo.MyOrderValues;
```

## Tiebreakers

In this section, I want to introduce a new technique based on aggregates to solve tiebreaker problems, which I started discussing in Chapter 6. I'll use the same example as I used there—returning the most recent order for each employee—using different combinations of tiebreaker attributes that uniquely identify an order for each employee. Keep in mind that the performance of the solutions that use subqueries depends very strongly on indexing. That is, you need an index on the partitioning column, sort column, and tiebreaker attributes. But in practice, you don't always have the option of adding as many indexes as you like. The subquery-based solutions will greatly suffer in performance from a lack of appropriate indexes. Using aggregation techniques, you'll see that the solution yields reasonable performance even when an optimal index is not in place—in fact, even when no good index is in place.

Let's start by using `MAX(orderid)` as the tiebreaker. To recap, you're after the most recent order for each employee, and if there's a tie for most recent, choose the order with the largest ID. For each employee's most recent order, you're supposed to return the columns `empid`, `orderdate`, `orderid`, `custid`, and `requiredate`. 
The aggregate technique to solve the problem applies the following logical idea, given here in pseudocode:

```sql
SELECT empid, MAX(orderdate, orderid, custid, requireddate)
FROM Sales.Orders
GROUP BY empid;
```

This idea can’t be expressed directly in T-SQL, so don’t try to run this query. The idea here is to select for each `empid`, the row with largest `orderdate` (most recent), then largest `orderid`—the tiebreaker—among orders with the most recent `orderdate`. Because the combination `empid`, `orderdate`, `orderid` is already unique, there will be no further ties to break, and the other attributes (`custid` and `requireddate`) are simply returned from the selected row. Because a MAX of more than one attribute does not exist in T-SQL, you must mimic it somehow. One way is by merging the attributes into a single input to the MAX function, then extracting back the individual elements in an outer query.

The question is this: What technique should you use to merge the attributes? The trick is to convert each attribute to a fixed-width string and concatenate the strings. You must convert the attributes to strings in a way that doesn’t change the sorting order. When dealing exclusively with nonnegative numbers, you can get by with an arithmetic calculation instead of concatenation. For example, say you have the numbers `m` and `n`, each with a valid range of 1 through 999. To merge `m` and `n`, use the following formula: 

```
m*1000 + n AS r.
```

You can easily extract the individual pieces later: `r` divided by 1000 is `m`, and `r` modulo 1000 is `n`. However, in many cases you may have nonnumeric data to concatenate, so arithmetic wouldn’t be possible. You might want to consider converting all values to fixed-width character strings (`CHAR(n)` or `NCHAR(n)`) or to fixed-width binary strings (`BINARY(n)`).

Here’s an example of returning the most recent order for each employee, where `MAX(orderid)` is the tiebreaker, using binary concatenation:

```sql
SELECT empid,
    CAST(SUBSTRING(binstr, 1, 8) AS DATETIME) AS orderdate,
    CAST(SUBSTRING(binstr, 9, 4) AS INT) AS orderid,
    CAST(SUBSTRING(binstr, 13, 4) AS INT) AS custid,
    CAST(SUBSTRING(binstr, 17, 8) AS DATETIME) AS requiredate
FROM (SELECT empid,
            MAX(CAST(orderdate AS BINARY(8))
               + CAST(orderid AS BINARY(4))
               + CAST(custid AS BINARY(4))
               + CAST(requiredate AS BINARY(8))) AS binstr
    FROM Sales.Orders
    GROUP BY empid) AS D;
```

The derived table `D` contains the maximum concatenated string for each employee. Notice that each value was converted to the appropriate fixed-size string before concatenation based on its data type (DATETIME—8 bytes, INT—4 bytes, and so on).
**Note** When you convert numbers to binary strings, only nonnegative values preserve their original sort order. As for DATETIME values, as long as they are not earlier than the base date January 1st, 1900, when converted to binary, the values preserve the original sort behavior. Values of the new DATE data type, however, do not preserve their sort behavior when converted to binary. As for character strings, converting them to binary values changes their sort order to one like a binary collation would define. Also note that preserving the original sort order is required only up to the point where uniqueness of a row per group is guaranteed (orderdate + orderid in our case).

The outer query uses `SUBSTRING` to extract the individual elements, and it converts them back to their original data types.

The real benefit in this solution is that it scans the data only once regardless of whether you have a good index. If you do, you'll probably get an ordered scan of the index and a sort-based aggregate (a stream aggregate). If you don't have a good index—as is the case here—you'll probably get a hash-based aggregate, as you can see in Figure 8-1.

![FIGURE 8-1 Execution plan for a tiebreaker query](image)

Things get trickier when the sort columns and tiebreaker attributes have different sort directions within them. For example, suppose the tiebreaker was `MIN(orderid)`. In that case, you would need to apply `MAX` to `orderdate` and `MIN` to `orderid`. There is a logical solution when the attribute with the opposite direction is numeric. Say you need to calculate the `MIN` value of a nonnegative integer column `n`, using only `MAX`, and you need to use binary concatenation. You can get the minimum by using `<maxint> - MAX(<maxint> - n)`.

The following query incorporates this logical technique:

```sql
SELECT empid, 
  CAST(SUBSTRING(binstr, 1, 8) AS DATETIME) AS orderdate, 
  2147483647 - CAST(SUBSTRING(binstr, 9, 4) AS INT) AS orderid, 
  CAST(SUBSTRING(binstr, 13, 4) AS INT) AS custid, 
  CAST(SUBSTRING(binstr, 17, 8) AS DATETIME) AS requiredate 
FROM (SELECT empid, 
  MAX(CAST(orderdate AS BINARY(8))) AS orderdate, 
  MAX(2147483647 - orderid AS BINARY(4)) AS orderid, 
  MAX(custid AS BINARY(4)) AS custid, 
  MAX(requiredate AS BINARY(8)) AS requiredate 
  FROM Sales.Orders 
  GROUP BY empid) AS D;
```

Another technique to calculate the minimum by using the `MAX` function is based on bitwise manipulation and works with nonnegative integers. The minimum value of a column `n` is equal to `~MAX(~n)`, where `~` is the bitwise NOT operator.
The following query incorporates this technique:

```sql
SELECT empid,
       CAST(SUBSTRING(binstr, 1, 8) AS DATETIME) AS orderdate,
       ~CAST(SUBSTRING(binstr, 9, 4) AS INT) AS orderid,
       CAST(SUBSTRING(binstr, 13, 4) AS INT) AS custid,
       CAST(SUBSTRING(binstr, 17, 8) AS DATETIME) AS requiredate
FROM (SELECT empid,
            MAX(CAST(orderdate AS BINARY(8))
            + ~CAST(orderid AS BINARY(4))
            + custid AS BINARY(4))
            AS binstr
       FROM Sales.Orders
       GROUP BY empid) AS D;
```

Of course, you can play with the tiebreakers you’re using in any way you like. For example, the following query returns the most recent order for each employee, using \(\text{MAX(requiredate)}\), \(\text{MAX(orderid)}\) as the tiebreaker:

```sql
SELECT empid,
       CAST(SUBSTRING(binstr, 1, 8) AS DATETIME) AS orderdate,
       CAST(SUBSTRING(binstr, 9, 8) AS DATETIME) AS requiredate,
       CAST(SUBSTRING(binstr, 17, 4) AS INT) AS orderid,
       CAST(SUBSTRING(binstr, 21, 4) AS INT) AS custid
FROM (SELECT empid,
            MAX(CAST(orderdate AS BINARY(8))
            + CAST(requiredate AS BINARY(8))
            + ~CAST(orderid AS BINARY(4))
            + custid AS BINARY(4))
            AS binstr
       FROM Sales.Orders
       GROUP BY empid) AS D;
```

**Running Aggregations**

Running aggregations are aggregations of data over a sequence (typically temporal). Running aggregate problems have many variations, and I’ll describe several important ones here.

In my examples, I’ll use a summary table called EmpOrders that contains one row for each employee and month, with the total quantity of orders made by that employee in that month. Run the following code to create the EmpOrders table and populate it with sample data:

```sql
USE tempdb;

IF OBJECT_ID('dbo.EmpOrders') IS NOT NULL DROP TABLE dbo.EmpOrders;

CREATE TABLE dbo.EmpOrders
(
    empid    INT  NOT NULL,
    ordmonth DATE NOT NULL,
```
Insert INTO dbo.EmpOrders(empid, ordmonth, qty)
SELECT O.empid,
    DATEADD(month, DATEDIFF(month, 0, O.orderdate), 0) AS ordmonth,
    SUM(qty) AS qty
FROM InsideTSQl2008.Sales.Orders AS O
JOIN InsideTSQl2008.Sales.OrderDetails AS OD
    ON O.orderid = OD.orderid
GROUP BY empid,
    DATEADD(month, DATEDIFF(month, 0, O.orderdate), 0);

**Tip** I will represent each month by its start date stored as a DATE. This allows flexible manipulation of the data using date-related functions. Of course, I’ll ignore the day part of the value in my calculations.

Run the following query to get the contents of the EmpOrders table:

```
SELECT empid, CONVERT(VARCHAR(7), ordmonth, 121) AS ordmonth, qty
FROM dbo.EmpOrders
ORDER BY empid, ordmonth;
```

This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>empid</th>
<th>ordmonth</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2006-07</td>

</table>

I’ll discuss three types of running aggregation problems: cumulative, sliding, and year-to-date (YTD).
Cumulative Aggregations

Cumulative aggregations accumulate data from the first element within the sequence up to the current point. For example, imagine the following request: for each employee and month, return the total quantity and average monthly quantity from the beginning of the employee’s activity through the month in question.

Recall the techniques for calculating row numbers without using the built-in ROW_NUMBER function; using these techniques, you scan the same rows we need here to calculate the total quantities. The difference is that for row numbers you used the aggregate COUNT, and here you’ll use the aggregates SUM and AVG. I demonstrated two set-based solutions to calculate row numbers without the ROW_NUMBER function—one using subqueries and one using joins. In the solution using joins, I applied what I called an expand-collapse technique. To me, the subquery solution is much more intuitive than the join solution, with its artificial expand-collapse technique. So, when there’s no performance difference, I’d rather use subqueries. Typically, you won’t see a performance difference when only one aggregate is involved because the plans would be similar. However, when you request multiple aggregates, the subquery solution might result in a plan that scans the data separately for each aggregate. Compare this to the plan for the join solution, which typically calculates all aggregates during a single scan of the source data.

So my choice is usually simple—use a subquery for one aggregate and use a join for multiple aggregates. The following query applies the expand-collapse approach to produce the desired result:

```
SELECT O1.empid, CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth,
       O1.qty AS qtythismonth, SUM(O2.qty) AS totalqty,
       CAST(AVG(1.*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
     JOIN dbo.EmpOrders AS O2
         ON O2.empid = O1.empid
         AND O2.ordmonth <= O1.ordmonth
GROUP BY O1.empid, O1.ordmonth, O1.qty
ORDER BY O1.empid, O1.ordmonth;
```

This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>empid</th>
<th>ordmonth</th>
<th>qtythismonth</th>
<th>totalqty</th>
<th>avgqty</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2006-07</td>
<td>121</td>
<td>121</td>
<td>121.00</td>
</tr>
<tr>
<td>1</td>
<td>2006-08</td>
<td>247</td>
<td>368</td>
<td>184.00</td>
</tr>
<tr>
<td>1</td>
<td>2006-09</td>
<td>255</td>
<td>623</td>
<td>207.67</td>
</tr>
<tr>
<td>1</td>
<td>2006-10</td>
<td>143</td>
<td>766</td>
<td>191.50</td>
</tr>
<tr>
<td>1</td>
<td>2006-11</td>
<td>318</td>
<td>1084</td>
<td>216.80</td>
</tr>
<tr>
<td>1</td>
<td>2006-12</td>
<td>536</td>
<td>1620</td>
<td>270.00</td>
</tr>
<tr>
<td>1</td>
<td>2007-01</td>
<td>304</td>
<td>1924</td>
<td>274.86</td>
</tr>
<tr>
<td>1</td>
<td>2007-02</td>
<td>168</td>
<td>2092</td>
<td>261.50</td>
</tr>
<tr>
<td>1</td>
<td>2007-03</td>
<td>275</td>
<td>2367</td>
<td>263.00</td>
</tr>
<tr>
<td>1</td>
<td>2007-04</td>
<td>20</td>
<td>2387</td>
<td>238.70</td>
</tr>
</tbody>
</table>

...
Now let’s say that you are asked to return only one aggregate (say, total quantity). You can safely use the subquery approach:

```
SELECT O1.empid, CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth,
       O1.qty AS qtythismonth,
       (SELECT SUM(O2.qty)
        FROM dbo.EmpOrders AS O2
        WHERE O2.empid = O1.empid
        AND O2.ordmonth <= O1.ordmonth) AS totalqty
FROM dbo.EmpOrders AS O1
GROUP BY O1.empid, O1.ordmonth, O1.qty;
```

As was the case for calculating row numbers based on subqueries or joins, when calculating running aggregates based on similar techniques, the $N^2$ performance issues I discussed before apply once again. Because running aggregates typically are calculated on a fairly small number of rows per group, you won’t be adversely affected by performance issues, assuming you have appropriate indexes (keyed on grouping columns, then sort columns, and including covering columns).

Let $p$ be the number of partitions involved (employees in our case), let $n$ be the average number of rows per partition (months in our case), and let $a$ be the number of aggregates involved. The total number of rows scanned using the join approach can be expressed as $pn + p(n+n^2)/2$ and as $pn + ap(n+n^2)/2$ using the subquery approach because with subqueries the optimizer uses a separate scan per subquery. It’s important to note that the $N^2$ complexity is relevant to the partition size and not the table size. If the number of rows in the table grows by a factor of $f$ but the partition size doesn’t change, the run time increases by a factor of $f$ as well. If, on the other hand, the average partition size grows by a factor of $f$, the run time increases by a factor of $f^2$. With small partitions (say, up to several dozen rows), this set-based solution provides reasonable performance. With large partitions, a cursor solution would be faster despite the overhead associated with row-by-row manipulation because a cursor scans the rows only once, and the per-row overhead is constant.

**Note** ANSI SQL provides support for running aggregates by means of aggregate window functions. SQL Server 2005 introduced the OVER clause for aggregate functions only with the PARTITION BY clause, and unfortunately SQL Server 2008 didn’t enhance the OVER clause further. Further enhancements are currently planned for the next major release of SQL Server—SQL
Server 11. Per ANSI SQL—and I hope in future versions of SQL Server—you could provide a solution relying exclusively on window functions, like so:

```sql
SELECT empid, CONVERT(VARCHAR(7), ordmonth, 121) AS ordmonth, qty,
       SUM(O2.qty) OVER(PARTITION BY empid
                        ORDER BY ordmonth
                        ROWS BETWEEN UNBOUNDED PRECEDING
                        AND CURRENT ROW) AS totalqty,
       CAST(AVG(1.*O2.qty) OVER(PARTITION BY empid
                                ORDER BY ordmonth
                                ROWS BETWEEN UNBOUNDED PRECEDING
                                AND CURRENT ROW) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders;
```

When this code is finally supported in SQL Server, you can expect dramatic performance improvements and obviously much simpler queries. Being familiar with the way ranking calculations based on the OVER clause are currently optimized, you should expect running aggregates based on the OVER clause to be optimized similarly. That is, given a good index to support the request, you should expect the plan to involve a single ordered scan of the data. Then the total number of rows scanned would simply be the number of rows in the table \((pn)\).

You might also be requested to filter the data—for example, return monthly aggregates for each employee only for months before the employee reached a certain target. Typically, you’ll have a target for each employee stored in a Targets table that you’ll need to join to. To make this example simple, I’ll assume that all employees have the same target total quantity—1,000. In practice, you’ll use the target attribute from the Targets table. Because you need to filter an aggregate, not an attribute, you must specify the filter expression (in this case, \(SUM(O2.qty) < 1000\)) in the HAVING clause, not the WHERE clause. The solution is as follows:

```sql
SELECT O1.empid, CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth,
       O1.qty AS qtythismonth, SUM(O2.qty) AS totalqty,
       CAST(AVG(1.*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
JOIN dbo.EmpOrders AS O2
  ON O2.empid = O1.empid
     AND O2.ordmonth <= O1.ordmonth
GROUP BY O1.empid, O1.ordmonth, O1.qty
HAVING SUM(O2.qty) < 1000
ORDER BY O1.empid, O1.ordmonth;
```

This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>empid</th>
<th>ordmonth</th>
<th>qtythismonth</th>
<th>totalqty</th>
<th>avgqty</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2006-07</td>
<td>121</td>
<td>121</td>
<td>121.00</td>
</tr>
<tr>
<td>1</td>
<td>2006-08</td>
<td>247</td>
<td>368</td>
<td>184.00</td>
</tr>
<tr>
<td>1</td>
<td>2006-09</td>
<td>255</td>
<td>623</td>
<td>207.67</td>
</tr>
<tr>
<td>1</td>
<td>2006-10</td>
<td>143</td>
<td>766</td>
<td>191.50</td>
</tr>
<tr>
<td>2</td>

<td>50</td>
<td>50</td>
<td>50.00</td>
</tr>
<tr>
<td>2</td>
<td>2006-08</td>
<td>94</td>
<td>144</td>
<td>72.00</td>
</tr>
<tr>
<td>2</td>
<td>2006-09</td>
<td>137</td>
<td>281</td>
<td>93.67</td>
</tr>
<tr>
<td>2</td>
<td>2006-10</td>
<td>248</td>
<td>529</td>
<td>132.25</td>
</tr>
</tbody>
</table>
Things get a bit tricky if you also need to include the rows for those months in which the employees reached their target. If you specify $\text{SUM(O2.qty)} \leq 1000$ (that is, write $\leq$ instead of $<$), you still won’t get the row in which the employee reached the target unless the total through that month is exactly 1,000. But remember that you have access to both the cumulative total and the current month’s quantity, and using these two values together, you can solve this problem. If you change the HAVING filter to $\text{SUM(O2.qty)} - \text{O1.qty} < 1000$, you get the months in which the employee’s total quantity, excluding the current month’s orders, had not reached the target. In particular, the first month in which an employee reached or exceeded the target satisfies this new criterion, and that month will appear in the results. The complete solution follows:

```sql
SELECT O1.empid, CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth, O1.qty AS qtythismonth, SUM(O2.qty) AS totalqty, CAST(AVG(1.*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
JOIN dbo.EmpOrders AS O2
ON O2.empid = O1.empid AND O2.ordmonth <= O1.ordmonth
GROUP BY O1.empid, O1.ordmonth, O1.qty
HAVING SUM(O2.qty) - O1.qty < 1000
ORDER BY O1.empid, O1.ordmonth;
```

This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>empid</th>
<th>ordmonth</th>
<th>qtythismonth</th>
<th>totalqty</th>
<th>avgqty</th>
</tr>
</thead>
<tbody>

<td>186.29</td>
</tr>
</tbody>
</table>
Note You might have another solution in mind that seems like a plausible and simpler alternative—to leave the SUM condition alone but change the join condition to \( O2.ordmonth < O1.ordmonth \). This way, the query would select rows where the total through the previous month did not meet the target. However, in the end, this solution is not any easier (the AVG is hard to generate, for example); what’s worse is that you might come up with a solution that does not work for employees who reach the target in their first month.

Tip If you want to return no fewer than a certain number of rows per partition, simply add the criterion \( OR \ COUNT(*) \leq <\text{min\_num\_of\_rows}> \) to the HAVING clause. This technique works well in our case since the base table contains one row per result row/group.

Suppose you’re interested in seeing results only for the specific month in which the employee reached the target of 1,000, without seeing results for preceding months. What’s true for only those rows in the output of the last query? You’re looking for rows where the total quantity is greater than or equal to 1,000. Simply add this criterion to the HAVING filter. Here’s the query followed by its output:

```
SELECT O1.empid, CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth,
       O1.qty AS qtythismonth, SUM(O2.qty) AS totalqty,
       CAST(AVG(1.*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
JOIN dbo.EmpOrders AS O2
ON O2.empid = O1.empid
   AND O2.ordmonth <= O1.ordmonth
GROUP BY O1.empid, O1.ordmonth, O1.qty
HAVING SUM(O2.qty) - O1.qty < 1000
       AND SUM(O2.qty) >= 1000
ORDER BY O1.empid, O1.ordmonth;
```

</table>

**Sliding Aggregations**

Sliding aggregates are calculated over a sliding window in a sequence (again, typically temporal), as opposed to being calculated from the beginning of the sequence until the current point. A *moving average*—such as the employee’s average quantity over the last three months—is one example of a sliding aggregate.
**Note** Without clarification, expressions such as “last three months” are ambiguous. The last three months could mean the previous three months (*not including this month*), or it could mean the previous two months *along with this month*. When you get a problem like this, be sure you know precisely what window of time you are using for aggregation—for a particular row, exactly when does the window begin and end?

In our example, the window of time is this: greater than the point in time starting three months ago and smaller than or equal to the current point in time. Note that this definition works well even in cases where you track finer time granularities than a month (including day, hour, minute, second, millisecond, microsecond, and nanosecond). This definition also addresses implicit conversion issues resulting from the accuracy level supported by SQL Server for the DATETIME data type—3.33 milliseconds. To avoid implicit conversion issues, it’s wiser to use > and <= predicates than the BETWEEN predicate.

The main difference between the solution for cumulative aggregates and the solution for sliding aggregates is in the join condition (or in the subquery’s filter in the case of the alternate solution using subqueries). Instead of using $O2.ordmonth <= O1.current_month$, you use $O2.ordmonth > three\_months\_before\_current$ AND $O2.ordmonth <= O1.current_month$. In T-SQL, this translates to the following query:

```sql
SELECT O1.empid,
       CONVERT(VARCHAR(7), O1.ordmonth, 121) AS tomonth,
       O1.qty AS qtythismonth,
       SUM(O2.qty) AS totalqty,
       CAST(AVG(1.0*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
     JOIN dbo.EmpOrders AS O2
       ON O2.empid = O1.empid
       AND (O2.ordmonth > DATEADD(month, -3, O1.ordmonth)
            AND O2.ordmonth <= O1.ordmonth)
GROUP BY O1.empid, O1.ordmonth, O1.qty
ORDER BY O1.empid, O1.ordmonth;
```

This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>empid</th>
<th>tomonth</th>
<th>qtythismonth</th>
<th>totalqty</th>
<th>avgqty</th>
</tr>
</thead>
<tbody>
<tr>

<td>2006-10</td>
<td>248</td>
<td>479</td>
<td>159.67</td>
</tr>
<tr>
<td>2</td>
<td>2006-11</td>
<td>237</td>
<td>622</td>
<td>207.33</td>
</tr>
</tbody>
</table>
Note that this solution includes aggregates for three-month periods that don’t include three months of actual data. If you want to return only periods with three full months accumulated, without the first two periods that do not cover three months, you can add the criterion $\text{MIN}(O2.\text{ordmonth}) = \text{DATEADD}(\text{month}, -2, O1.\text{ordmonth})$ to the HAVING filter.

**Year-to-Date (YTD)**

YTD aggregates accumulate values from the beginning of a period based on some date and time unit (say, a year) until the current point. The calculation is very similar to the sliding aggregates solution. The only difference is the lower bound provided in the query’s filter, which is the calculation of the beginning of the year. For example, the following query returns YTD aggregates for each employee and month:

```sql
SELECT O1.empid,
CONVERT(VARCHAR(7), O1.ordmonth, 121) AS ordmonth,
O1.qty AS qtythismonth,
SUM(O2.qty) AS totalqty,
CAST(AVG(1.0*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders AS O1
JOIN dbo.EmpOrders AS O2
ON O2.empid = O1.empid
AND (O2.ordmonth >= CAST(CAST(YEAR(O1.ordmonth) AS CHAR(4)) + '0101' AS DATETIME)
    AND CURRENT ROW) AS totalqty,
CAST(AVG(1.0*O2.qty) AS NUMERIC(12, 2)) AS avgqty
FROM dbo.EmpOrders;
```
This query generates the following output, shown here in abbreviated form:

<table>

### Pivoting

Pivoting is a technique that allows you to rotate rows to columns, possibly performing aggregations along the way. The number of applications for pivoting is simply astounding. In this section, I’ll present a few, including pivoting attributes in an open schema environment, solving relational division problems, and formatting aggregated data. Later in the chapter and also in later chapters in the book, I’ll show additional applications.

### Pivoting Attributes

I’ll use *open schema* as the scenario for pivoting attributes. Open schema is a design problem describing an environment that needs to deal with frequent schema changes. The relational model and SQL were conceived to handle frequent changes and requests for data via SQL’s data manipulation language (DML). However, SQL’s data definition language (DDL) was not conceived to support frequent schema changes. Whenever you need to add new entities, you must create new tables; whenever existing entities change their structures, you must add, alter, or drop columns. Such changes usually require downtime of the affected objects, and they also bring about substantial revisions to the application.

You can choose from several ways to model an open schema environment, each of which has advantages and disadvantages. One of those models is known as Entity Attribute
Value (EAV) and also as the narrow representation of data. In this model, you store all data in a single table, where each attribute value resides in its own row along with the entity or object ID and the attribute name or ID. You represent the attribute values using the data type SQL_VARIANT to accommodate multiple attribute types in a single column.

In my examples, I’ll use the OpenSchema table, which you can create and populate by running the following code:

```
USE tempdb;

IF OBJECT_ID('dbo.OpenSchema') IS NOT NULL DROP TABLE dbo.OpenSchema;

CREATE TABLE dbo.OpenSchema
(
    objectid INT          NOT NULL,
    attribute NVARCHAR(30) NOT NULL,
    value     SQL_VARIANT  NOT NULL,
    PRIMARY KEY (objectid, attribute)
);

GO

INSERT INTO dbo.OpenSchema(objectid, attribute, value) VALUES
(1, N'attr1', CAST(CAST('ABC'      AS VARCHAR(10))   AS SQL_VARIANT)),
(1, N'attr2', CAST(CAST(10         AS INT)           AS SQL_VARIANT)),
(1, N'attr3', CAST(CAST('20070101' AS SMALLDATETIME) AS SQL_VARIANT)),
(2, N'attr2', CAST(CAST(12         AS INT)           AS SQL_VARIANT)),
(2, N'attr3', CAST(CAST('20090101' AS SMALLDATETIME) AS SQL_VARIANT)),
(2, N'attr4', CAST(CAST('Y'        AS CHAR(1))       AS SQL_VARIANT)),
(2, N'attr5', CAST(CAST(13.7       AS NUMERIC(9,3))  AS SQL_VARIANT)),
(3, N'attr1', CAST(CAST('XYZ'      AS VARCHAR(10))   AS SQL_VARIANT)),
(3, N'attr2', CAST(CAST(20         AS INT)           AS SQL_VARIANT)),
(3, N'attr3', CAST(CAST('20080101' AS SMALLDATETIME) AS SQL_VARIANT));

-- show the contents of the table
SELECT * FROM dbo.OpenSchema;
```

This generates the following output:

```
objectid | attribute | value
---------|-----------|--------
 1        | attr1     | ABC
 1        | attr2     | 10
 1        | attr3     | 2007-01-01 00:00:00.000
 2        | attr2     | 12
 2        | attr3     | 2009-01-01 00:00:00.000
 2        | attr4     | Y
 2        | attr5     | 13.700
 3        | attr1     | XYZ
 3        | attr2     | 20
 3        | attr3     | 2008-01-01 00:00:00.000
```

Representing data this way allows logical schema changes to be implemented without adding, altering, or dropping tables and columns—you use DML INSERTs, UPDATEs, and DELETEs instead.
Of course, other aspects of working with the data (such as enforcing integrity, tuning, and querying) become more complex and expensive with such a representation. As mentioned, there are other approaches to dealing with open schema environments—for example, storing the data in XML format, using a *wide* representation of data, using CLR types, and others. However, when you weigh the advantages and disadvantages of each representation, you might find the EAV approach demonstrated here more favorable in some scenarios.

Keep in mind that this representation of the data requires very complex queries even for simple requests because different attributes of the same entity instance are spread over multiple rows. Before you query such data, you might want to rotate it to a traditional form with one column for each attribute—perhaps store the result in a temporary table, index it, query it, and then get rid of the temporary table. To rotate the data from its open schema form into a traditional form, you need to use a pivoting technique.

In the following section, I’ll describe the steps involved in solving pivoting problems. I’d like to point out that to understand the steps of the solution, it can be very helpful if you think about query logical processing phases, which I described in detail in Chapter 1, “Logical Query Processing.” I discussed the query processing phases involved with the native PIVOT table operator, but those phases apply just as well to the standard solution that does not use this proprietary operator. Moreover, in the standard solution the phases are more apparent in the code, while using the PIVOT operator they are implicit.

The first step you might want to try when solving pivoting problems is to figure out how the number of rows in the result correlates to the number of rows in the source data. Here, you need to create a single result row out of the multiple base rows for each object. In SQL, this translates to grouping rows. So our first logical processing phase in pivoting is a *grouping* phase, and the associated element (the element you need to group by) is the `objectid` column.

As the next step in a pivoting problem, you can think in terms of the result columns. You need a result column for each unique attribute. Because the data contains five unique attributes (`attr1`, `attr2`, `attr3`, `attr4`, and `attr5`), you need five expressions in the SELECT list. Each expression is supposed to extract, out of the rows belonging to the grouped object, the value corresponding to a specific attribute. You can think of this logical phase as a *spreading* phase—you need to spread the values, or shift them, from the source column (value in our case) to the corresponding target column. As for the element that dictates where to spread the values, or the *spread by* element, in our case it is the attribute column. This spreading activity can be done with the following CASE expression, which in this example is applied to the attribute `attr2`:

```sql
CASE WHEN attribute = 'attr2' THEN value END
```

Remember that with no ELSE clause, CASE assumes an implicit ELSE NULL. The CASE expression just shown yields NULL for rows where `attribute` does not equal `attr2` and yields `value` when `attribute` does equal `attr2`. This means that among the rows with a given value of `objectid` (say, 1), the CASE expression would yield several NULLs and, at most, one known value.
(10 in our example), which represents the value of the target attribute (attr2 in our example) for the given objectid.

The third phase in pivoting attributes is to extract the known value (if it exists) out of the set of NULLs and the known value. You have to use an aggregate for this purpose because, as you’ll recall, the query involves grouping. The trick to extracting the one known value is to use MAX or MIN. Both ignore NULLs and will return the one non-NULL value present because both the minimum and the maximum of a set containing one value is that value. So our third logical processing phase in pivoting is an aggregation phase. The aggregation element is the value column, and the aggregate function is MAX. Using the previous expression implementing the second phase with attr2, here’s the revised expression including the aggregation as well:

\[
\text{MAX(CASE WHEN attribute = 'attr2' THEN value END) AS attr2}
\]

Here’s the complete query that pivots the attributes from OpenSchema:

```sql
SELECT objectid, 
       MAX(CASE WHEN attribute = 'attr1' THEN value END) AS attr1, 
       MAX(CASE WHEN attribute = 'attr2' THEN value END) AS attr2, 
       MAX(CASE WHEN attribute = 'attr3' THEN value END) AS attr3, 
       MAX(CASE WHEN attribute = 'attr4' THEN value END) AS attr4, 
       MAX(CASE WHEN attribute = 'attr5' THEN value END) AS attr5
FROM dbo.OpenSchema
GROUP BY objectid;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>objectid</th>
<th>attr1</th>
<th>attr2</th>
<th>attr3</th>
<th>attr4</th>
<th>attr5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>ABC</td>
<td>10</td>
<td>2007-01-01 00:00:00.000</td>
<td>NULL</td>
<td>NULL</td>
</tr>
<tr>
<td>2</td>
<td>NULL</td>
<td>12</td>
<td>2009-01-01 00:00:00.000</td>
<td>Y</td>
<td>13.700</td>
</tr>
<tr>
<td>3</td>
<td>XYZ</td>
<td>20</td>
<td>2008-01-01 00:00:00.000</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

**Note** To write this query, you have to know the names of the attributes. If you don’t, you’ll need to construct the query string dynamically. I’ll provide an example later in the chapter.

This technique for pivoting data is very efficient because it scans the base table only once.

SQL Server supports a native specialized table operator for pivoting called PIVOT. This operator does not provide any special advantages over the technique I just showed, except that it allows for shorter code. It doesn’t support dynamic pivoting, and underneath the covers, it applies very similar logic to the one I presented in the last solution. So you probably won’t even find noticeable performance differences. At any rate, here’s how you would pivot the OpenSchema data using the PIVOT operator:

```sql
SELECT objectid, attr1, attr2, attr3, attr4, attr5
FROM dbo.OpenSchema
PIVOT(MAX(value) FOR attribute 
      IN([attr1],[attr2],[attr3],[attr4],[attr5])) AS P;
```
Within this solution, you can identify all the elements I used in the previous solution. The inputs to the PIVOT operator are as follows:

- The aggregate function applied to the aggregation element. In our case, it’s `MAX(value)`, which extracts the single non-NULL value corresponding to the target attribute. In other cases, you might have more than one non-NULL value per group and want a different aggregate (for example, SUM or AVG).

- Following the FOR keyword, the name of the spread by element (`attribute`, in our case). This is the source column holding the values that become the target column names.

- The list of actual target column names in parentheses following the keyword IN.

As you can see, in the parentheses of the PIVOT operator, you specify the aggregate function and aggregation element and the spread by element and spreading values but not the group by elements. This is a problematic aspect of the syntax of the PIVOT operator—the grouping elements are implicitly derived from what was not specified. The grouping elements are the list of all columns from the input table to the PIVOT operator that were not mentioned as either the aggregation or the spreading elements. In our case, `objectid` is the only column left. If you unintentionally query the base table directly, you might end up with undesired grouping. If new columns will be added to the table in the future, those columns will be implicitly added to PIVOT’s grouping list. Therefore, it is strongly recommended that you apply the PIVOT operator not to the base table directly but rather to a table expression (derived table or CTE) that includes only the elements relevant to the pivoting activity. This way, you can control exactly which columns remain besides the aggregation and spreading elements. Future column additions to the table won’t have any impact on what PIVOT ends up operating on. The following query demonstrates applying this approach to our previous query, using a derived table:

```sql
SELECT objectid, attr1, attr2, attr3, attr4, attr5
FROM (SELECT objectid, attribute, value FROM dbo.OpenSchema) AS D
PIVOT(MAX(value) FOR attribute
    IN([attr1],[attr2],[attr3],[attr4],[attr5])) AS P;
```

**Tip** The input to the aggregate function must be a base column from the PIVOT operator’s input table with no manipulation—it cannot be an expression (for example: `SUM(qty * price)`). If you want to provide the aggregate function with an expression as input, have the PIVOT operator operate on a derived table or CTE (as suggested for other reasons as well), and in the derived table query assign the expression with a column alias (`qty * price AS value`). Then, as far as the PIVOT operator is concerned, that alias is the name of a base column in its input table, so it is valid to use that column name as input to PIVOT’s aggregate function (`SUM(value)`).

Also, you cannot spread attributes from more than one column (the column that appears after the FOR keyword). If you need to pivot more than one column’s attributes (say, `empid` and `YEAR(orderdate)`), you can use a similar approach to the previous suggestion: in the derived table or CTE used as the input to the PIVOT operator, concatenate the values from all columns you want to use as the spreading elements and assign the expression with a column alias (`CAST(empid AS VARCHAR(10)) + '_' + CAST(YEAR(orderdate) AS CHAR(4)) AS emp_year`). Then, in the outer query, specify that column after PIVOT’s FOR keyword (FOR `emp_year` IN([1_2007], [1_2008], [1_2009], [2_2007], . . .)).
Relational Division

You can also use pivoting to solve relational division problems when the number of elements in the divisor set is fairly small. In my examples, I'll use the OrderDetails table, which you create and populate by running the following code:

```sql
USE tempdb;

IF OBJECT_ID('dbo.OrderDetails') IS NOT NULL
  DROP TABLE dbo.OrderDetails;

CREATE TABLE dbo.OrderDetails
(
  orderid   VARCHAR(10) NOT NULL,
  productid INT         NOT NULL,
  PRIMARY KEY(orderid, productid)
/* other columns */
);
GO

INSERT INTO dbo.OrderDetails(orderid, productid) VALUES
 ('A', 1),
 ('A', 2),
 ('A', 3),
 ('A', 4),
 ('B', 2),
 ('B', 3),
 ('B', 4),
 ('C', 3),
 ('C', 4),
 ('D', 4);
```

A classic relational division problem is to return orders that contain a certain basket of products—say, products 2, 3, and 4. You use a pivoting technique to rotate only the relevant products into separate columns for each order. Instead of returning an actual attribute value, you produce a 1 if the product exists in the order and a 0 otherwise. Create a derived table out of the pivot query, and in the outer query filter only orders that contain a 1 in all product columns. Here's the full query, which correctly returns orders A and B:

```sql
SELECT orderid
FROM (SELECT
    orderid,
    MAX(CASE WHEN productid = 2 THEN 1 END) AS P2,
    MAX(CASE WHEN productid = 3 THEN 1 END) AS P3,
    MAX(CASE WHEN productid = 4 THEN 1 END) AS P4
  FROM dbo.OrderDetails
  GROUP BY orderid) AS P
WHERE P2 = 1 AND P3 = 1 AND P4 = 1;
```
If you run only the derived table query, you get the following output with the pivoted products for each order:

<table>
<thead>
<tr>
<th>orderid</th>
<th>P2</th>
<th>P3</th>
<th>P4</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>C</td>
<td>NULL</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>D</td>
<td>NULL</td>
<td>NULL</td>
<td>1</td>
</tr>
</tbody>
</table>

To answer the request at hand using the new PIVOT operator, use the following query:

SELECT orderid
FROM (SELECT orderid, productid FROM dbo.OrderDetails) AS D
PIVOT(MAX(productid) FOR productid IN([2],[3],[4])) AS P

The aggregate function must accept a column as input, so I provided the productid itself. This means that if the product exists within an order, the corresponding value will contain the actual productid and not 1. That's why the filter looks a bit different here.

Note that you can make both queries more intuitive and similar to each other in their logic by using the COUNT aggregate instead of MAX. This way, both queries would produce a 1 where the product exists and a 0 where it doesn’t (instead of NULL). Here’s what the query that does not use the PIVOT operator looks like:

SELECT orderid
FROM (SELECT
    orderid,
    COUNT(CASE WHEN productid = 2 THEN productid END) AS P2,
    COUNT(CASE WHEN productid = 3 THEN productid END) AS P3,
    COUNT(CASE WHEN productid = 4 THEN productid END) AS P4
FROM dbo.OrderDetails
GROUP BY orderid) AS P
WHERE P2 = 1 AND P3 = 1 AND P4 = 1;

And here's the query you would use based on the PIVOT operator:

SELECT orderid
FROM (SELECT orderid, productid FROM dbo.OrderDetails) AS D
PIVOT(COUNT(productid) FOR productid IN([2],[3],[4])) AS P

**Aggregating Data**

You can also use a pivoting technique to format aggregated data, typically for reporting purposes. In my examples, I’ll use the Orders table, which you create and populate by running the code in Listing 8-1.
LISTING 8-1 Creating and populating the Orders table

```
SET NOCOUNT ON;
USE tempdb;

IF OBJECT_ID('dbo.Orders', 'U') IS NOT NULL DROP TABLE dbo.Orders;

CREATE TABLE dbo.Orders
(
    orderid   INT        NOT NULL,
    orderdate DATETIME   NOT NULL,
    empid     INT        NOT NULL,
    custid    VARCHAR(5) NOT NULL,
    qty       INT        NOT NULL,
    CONSTRAINT PK_Orders PRIMARY KEY(orderid)
);
GO

INSERT INTO dbo.Orders
(orderid, orderdate, empid, custid, qty)
VALUES
(30001, '20060802', 3, 'A', 10),
(10001, '20061224', 1, 'A', 12),
(10005, '20061224', 1, 'B', 20),
(40001, '20070109', 4, 'A', 40),
(10006, '20070118', 1, 'C', 14),
(20001, '20070212', 2, 'B', 12),
(40005, '20080212', 4, 'A', 10),
(20002, '20080216', 2, 'C', 20),
(30003, '20080418', 3, 'B', 15),
(30004, '20060418', 3, 'C', 22),
(30007, '20060907', 3, 'D', 30);

-- show the contents of the table
SELECT * FROM dbo.Orders;
```

This generates the following output:

<table>
<thead>
<tr>
<th>orderid</th>
<th>orderdate</th>
<th>empid</th>
<th>custid</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>10001</td>
<td>2006-12-24</td>
<td>1</td>
<td>A</td>
<td>12</td>
</tr>
<tr>
<td>10005</td>
<td>2006-12-24</td>
<td>1</td>
<td>B</td>
<td>20</td>
</tr>
<tr>
<td>10006</td>
<td>2007-01-18</td>
<td>1</td>
<td>C</td>
<td>14</td>
</tr>
<tr>
<td>20001</td>
<td>2007-02-12</td>
<td>2</td>
<td>B</td>
<td>12</td>
</tr>
<tr>
<td>20002</td>
<td>2008-02-16</td>
<td>2</td>
<td>C</td>
<td>20</td>
</tr>
<tr>
<td>30001</td>
<td>2006-08-02</td>
<td>3</td>
<td>A</td>
<td>10</td>
</tr>
<tr>
<td>30003</td>
<td>2008-04-18</td>
<td>3</td>
<td>B</td>
<td>15</td>
</tr>
<tr>
<td>30004</td>
<td>2006-04-18</td>
<td>3</td>
<td>C</td>
<td>22</td>
</tr>
<tr>
<td>30007</td>
<td>2006-09-07</td>
<td>3</td>
<td>D</td>
<td>30</td>
</tr>
<tr>
<td>40001</td>
<td>2007-01-09</td>
<td>4</td>
<td>A</td>
<td>40</td>
</tr>
<tr>
<td>40005</td>
<td>2008-02-12</td>
<td>4</td>
<td>A</td>
<td>10</td>
</tr>
</tbody>
</table>
Suppose you want to return a row for each customer, with the total yearly quantities in a different column for each year. As with all pivoting problems, it boils down to identifying the grouping, spreading, and aggregation elements. In this case, the grouping element is the `custid` column, the spreading element is the expression `YEAR(orderdate)`, and the aggregate function and element is `SUM(qty)`. What remains is simply to use the solution templates I provided previously. Here’s the solution that does not use the PIVOT operator, followed by its output:

```sql
SELECT custid,
    SUM(CASE WHEN orderyear = 2006 THEN qty END) AS [2006],
    SUM(CASE WHEN orderyear = 2007 THEN qty END) AS [2007],
    SUM(CASE WHEN orderyear = 2008 THEN qty END) AS [2008]
FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
    FROM dbo.Orders) AS D
GROUP BY custid;
```

<table>
<thead>
<tr>
<th>custid</th>
<th>2006</th>
<th>2007</th>
<th>2008</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>22</td>
<td>40</td>
<td>10</td>
</tr>
<tr>
<td>B</td>
<td>20</td>
<td>12</td>
<td>15</td>
</tr>
<tr>
<td>C</td>
<td>22</td>
<td>14</td>
<td>20</td>
</tr>
<tr>
<td>D</td>
<td>30</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

Here you can see the use of a derived table to isolate only the relevant elements for the pivoting activity (`custid, orderyear, qty`).

One of the main issues with this pivoting solution is that you might end up with lengthy query strings when the number of elements you need to rotate is large. It’s not a problem in this case because we are dealing with order years, and there usually aren’t that many, but it could be a problem in other cases when the spreading column has a large number of values. In an effort to shorten the query string, you can use a matrix table that contains a column and a row for each attribute that you need to rotate (`orderyear`, in this case). Only column values in the intersections of corresponding rows and columns contain the value 1, and the other column values are populated with a NULL or a 0, depending on your needs. Run the following code to create and populate the Matrix table:

```sql
USE tempdb;
GO

IF OBJECTPROPERTY(OBJECT_ID('dbo.Matrix'), 'IsUserTable') = 1
    DROP TABLE dbo.Matrix;
GO

CREATE TABLE dbo.Matrix
(
    orderyear INT NOT NULL PRIMARY KEY,
    y2006 INT NULL,
    y2007 INT NULL,
    y2008 INT NULL
);

INSERT INTO dbo.Matrix(orderyear, y2006) VALUES(2006, 1);
INSERT INTO dbo.Matrix(orderyear, y2007) VALUES(2007, 1);
INSERT INTO dbo.Matrix(orderyear, y2008) VALUES(2008, 1);
```
-- show the contents of the table
SELECT * FROM dbo.Matrix;

This generates the following output:

<table>
<thead>
<tr>
<th>orderyear</th>
<th>y2006</th>
<th>y2007</th>
<th>y2008</th>
</tr>
</thead>
<tbody>
<tr>
<td>2006</td>
<td>1</td>
<td>NULL</td>
<td>NULL</td>
</tr>
<tr>
<td>2007</td>
<td>NULL</td>
<td>1</td>
<td>NULL</td>
</tr>
<tr>
<td>2008</td>
<td>NULL</td>
<td>NULL</td>
<td>1</td>
</tr>
</tbody>
</table>

You join the base table (or table expression) with the Matrix table based on a match in *orderyear*. This means that each row from the base table will be matched with one row from Matrix—the one with the same *orderyear*. In that row, only the corresponding *orderyear*'s column value will contain a 1. So you can substitute the expression

```
SUM(CASE WHEN orderyear = <some_year> THEN qty END) AS [some_year]
```

with the logically equivalent expression

```
SUM(qty*y<some_year>) AS [some_year]
```

Here's what the full query looks like:

```sql
SELECT custid,
       SUM(qty*y2006) AS [2006],
       SUM(qty*y2007) AS [2007],
       SUM(qty*y2008) AS [2008]
FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
       FROM dbo.Orders) AS D
JOIN dbo.Matrix AS M ON D.orderyear = M.orderyear
GROUP BY custid;
```

If you need the number of orders instead of the sum of *qty*, in the original solution you produce a 1 instead of the *qty* column for each order and use the COUNT aggregate function, like so:

```sql
SELECT custid,
       COUNT(CASE WHEN orderyear = 2006 THEN 1 END) AS [2006],
       COUNT(CASE WHEN orderyear = 2007 THEN 1 END) AS [2007],
       COUNT(CASE WHEN orderyear = 2008 THEN 1 END) AS [2008]
FROM (SELECT custid, YEAR(orderdate) AS orderyear
       FROM dbo.Orders) AS D
GROUP BY custid;
```

This code generates the following output:

<table>
<thead>
<tr>
<th>custid</th>
<th>2006</th>
<th>2007</th>
<th>2008</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>2</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>C</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>D</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>
With the Matrix table, simply specify the column corresponding to the target year:

```sql
SELECT custid,
    COUNT(y2006) AS [2006],
    COUNT(y2007) AS [2007],
    COUNT(y2008) AS [2008]
FROM (SELECT custid, YEAR(orderdate) AS orderyear
    FROM dbo.Orders) AS D
JOIN dbo.Matrix AS M ON D.orderyear = M.orderyear
GROUP BY custid;
```

Of course, using the PIVOT operator, the query strings are pretty much as short as they can get. You don’t explicitly specify the CASE expressions: those are constructed behind the scenes for you (you can actually see them by looking at the properties of the aggregate operator in the plan). In short, you don’t need to use the Matrix table approach with the PIVOT operator. Here’s the query using the PIVOT operator to calculate total yearly quantities per customer:

```sql
SELECT *
FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
    FROM dbo.Orders) AS D
PIVOT(SUM(qty) FOR orderyear IN([2006],[2007],[2008])) AS P;
```

And here’s a query that counts the orders:

```sql
SELECT *
FROM (SELECT custid, YEAR(orderdate) AS orderyear
    FROM dbo.Orders) AS D
PIVOT(COUNT(orderyear) FOR orderyear IN([2006],[2007],[2008])) AS P;
```

Remember that static queries performing pivoting require you to know ahead of time the list of attributes you’re going to rotate. For dynamic pivoting, you need to construct the query string dynamically.

### Unpivoting

Unpivoting is the opposite of pivoting—namely, rotating columns to rows. Unpivoting is usually used to normalize data, but it has other applications as well.

**Note** Unpivoting is not an exact inverse of pivoting—it won’t necessarily allow you to regenerate source rows that were pivoted. However, for the sake of simplicity, think of it as the opposite of pivoting.

In my examples, I’ll use the PvtCustOrders table, which you create and populate by running the following code:

```sql
USE tempdb;

IF OBJECT_ID('dbo.PvtCustOrders') IS NOT NULL
    DROP TABLE dbo.PvtCustOrders;
GO
```
SELECT custid,
    COALESCE([2006], 0) AS [2006],
    COALESCE([2007], 0) AS [2007],
    COALESCE([2008], 0) AS [2008]
INTO dbo.PvtCustOrders
FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
    FROM dbo.Orders) AS D
    PIVOT(SUM(qty) FOR orderyear IN([2006],[2007],[2008])) AS P;

UPDATE dbo.PvtCustOrders
WHERE custid = 'D';

-- Show the contents of the table
SELECT * FROM dbo.PvtCustOrders;

This generates the following output:

<table>
<thead>
<tr>
<th>custid</th>
<th>2006</th>
<th>2007</th>
<th>2008</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>22</td>
<td>40</td>
<td>10</td>
</tr>
<tr>
<td>B</td>
<td>20</td>
<td>12</td>
<td>15</td>
</tr>
<tr>
<td>C</td>
<td>22</td>
<td>14</td>
<td>20</td>
</tr>
<tr>
<td>D</td>
<td>30</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

The goal in this case is to generate a result row for each customer and year, containing the customer ID (custid), order year (orderyear), and quantity (qty).

I’ll start with a solution that does not use the native UNPIVOT operator. Here as well, try to think in terms of logical query processing as described in Chapter 1.

The first step in the solution is to generate three copies of each base row—one for each year. You can achieve this by performing a cross join between the base table and a virtual auxiliary table that has one row per year. The SELECT list can then return custid and orderyear and also calculate the target year’s qty with the following CASE expression:

CASE orderyear
    WHEN 2006 THEN [2006]
    WHEN 2007 THEN [2007]
    WHEN 2008 THEN [2008]
END AS qty

You achieve unpivoting this way, but you also get rows corresponding to NULL values in the source table (for example, for customer D in years 2007 and 2008). To eliminate those rows, create a derived table out of the solution query and, in the outer query, eliminate the rows with the NULL in the qty column.

Note In practice, you’d typically store a 0 and not a NULL as the quantity for a customer with no orders in a certain year; the order quantity is known to be zero and not unknown. However, I used NULLs here to demonstrate the treatment of NULLs, which is a very common need in unpivoting problems.
Here’s the complete solution, followed by its output:

```sql
SELECT custid, orderyear, qty
FROM (SELECT custid, orderyear,
          CASE orderyear
            WHEN 2006 THEN [2006]
            WHEN 2007 THEN [2007]
            WHEN 2008 THEN [2008]
          END AS qty
       FROM dbo.PvtCustOrders
       CROSS JOIN
       (SELECT 2006 AS orderyear
        UNION ALL SELECT 2007
        UNION ALL SELECT 2008) AS OrderYears) AS D
WHERE qty IS NOT NULL;
```

```
custid | orderyear | qty
--------|-----------|------
A       | 2006      | 22   
A       | 2007      | 40   
A       | 2008      | 10   
B       | 2006      | 20   
B       | 2007      | 12   
B       | 2008      | 15   
C       | 2006      | 22   
C       | 2007      | 14   
C       | 2008      | 20   
D       | 2006      | 30   
D       | 2007      | 0    
D       | 2008      | 0    
```

As of SQL Server 2008, you can replace the current definition of the derived table D with a table value constructor based on the VALUES clause, like so:

```sql
SELECT custid, orderyear, qty
FROM (SELECT custid, orderyear,
          CASE orderyear
            WHEN 2006 THEN [2006]
            WHEN 2007 THEN [2007]
            WHEN 2008 THEN [2008]
          END AS qty
       FROM dbo.PvtCustOrders
       CROSS JOIN
       (VALUES(2006),(2007),(2008)) AS OrderYears(orderyear)) AS D
WHERE qty IS NOT NULL;
```

Either way, using the native proprietary UNPIVOT table operator is dramatically simpler, as the following query shows:

```sql
SELECT custid, orderyear, qty
FROM dbo.PvtCustOrders
UNPIVOT(qty FOR orderyear IN([2006],[2007],[2008])) AS U;
```

Unlike the PIVOT operator, I find the UNPIVOT operator simple and intuitive, and obviously it requires significantly less code than the alternative solutions. UNPIVOT’s first input is the target column name to hold the source column values (qty). Then, following the FOR keyword,
you specify the target column name to hold the source column names (orderyear). Finally, in the parentheses of the IN clause, you specify the source column names that you want to unpivot ([2006],[2007],[2008]).

**Tip** All source attributes that are unpivoted must share the same data type. If you want to unpivot attributes defined with different data types, create a derived table or CTE where you first convert all those attributes to SQL_VARIANT. The target column that will hold unpivoted values will also be defined as SQL_VARIANT, and within that column, the values will preserve their original types.

**Note** Like PIVOT, UNPIVOT requires a static list of column names to be rotated. Also, the UNPIVOT operator applies a logical phase that removes NULL rows. However, unlike in the other solutions where the removal of NULL rows is an optional phase, with the UNPIVOT operator it is not optional.

### Custom Aggregations

Custom aggregations are aggregations that are not provided as built-in aggregate functions—for example, concatenating strings, calculating products, performing bitwise manipulations, calculating medians, and others. In this section, I’ll provide solutions to several custom aggregate requests. Some techniques that I’ll cover are generic, in the sense that you can use similar logic for other aggregate requests; other techniques are specific to one kind of aggregate request.

**More Info** One of the generic custom aggregate techniques uses cursors. For details about cursors, including handling of custom aggregates with cursors, please refer to *Inside Microsoft SQL Server 2008: T-SQL Programming* (Microsoft Press, 2009).

In my examples, I’ll use the generic Groups table, which you create and populate by running the following code:

```sql
USE tempdb;

IF OBJECT_ID('dbo.Groups') IS NOT NULL DROP TABLE dbo.Groups;

CREATE TABLE dbo.Groups
(
    groupid VARCHAR(10) NOT NULL,
    memberid INT NOT NULL,
    string  VARCHAR(10) NOT NULL,
    val     INT NOT NULL,
    PRIMARY KEY (groupid, memberid)
);
GO
```

In my examples, I’ll use the generic Groups table, which you create and populate by running the following code:

```sql
USE tempdb;

IF OBJECT_ID('dbo.Groups') IS NOT NULL DROP TABLE dbo.Groups;

CREATE TABLE dbo.Groups
(
    groupid VARCHAR(10) NOT NULL,
    memberid INT NOT NULL,
    string  VARCHAR(10) NOT NULL,
    val     INT NOT NULL,
    PRIMARY KEY (groupid, memberid)
);
GO
```
INSERT INTO dbo.Groups(groupid, memberid, string, val) VALUES
('a', 3, 'stra1', 6),
('a', 9, 'stra2', 7),
('b', 2, 'strb1', 3),
('b', 4, 'strb2', 7),
('b', 5, 'strb3', 3),
('b', 9, 'strb4', 11),
('c', 3, 'strc1', 8),
('c', 7, 'strc2', 10),
('c', 9, 'strc3', 12);

-- Show the contents of the table
SELECT * FROM dbo.Groups;

This generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>memberid</th>
<th>string</th>
<th>val</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>3</td>
<td>stra1</td>
<td>6</td>
</tr>
<tr>
<td>a</td>
<td>9</td>
<td>stra2</td>
<td>7</td>
</tr>
<tr>
<td>b</td>
<td>2</td>
<td>strb1</td>
<td>3</td>
</tr>
<tr>
<td>b</td>
<td>4</td>
<td>strb2</td>
<td>7</td>
</tr>
<tr>
<td>b</td>
<td>5</td>
<td>strb3</td>
<td>3</td>
</tr>
<tr>
<td>b</td>
<td>9</td>
<td>strb4</td>
<td>11</td>
</tr>
<tr>
<td>c</td>
<td>3</td>
<td>strc1</td>
<td>8</td>
</tr>
<tr>
<td>c</td>
<td>7</td>
<td>strc2</td>
<td>10</td>
</tr>
<tr>
<td>c</td>
<td>9</td>
<td>strc3</td>
<td>12</td>
</tr>
</tbody>
</table>

The Groups table has a column representing the group (groupid), a column representing a unique identifier within the group (memberid), and some value columns (string and val) that need to be aggregated. I like to use such a generic form of data because it allows you to focus on the techniques and not on the data. Note that this is merely a generic form of a table containing data that you want to aggregate. For example, it could represent a Sales table where groupid stands for empid, val stands for qty, and so on.

**Custom Aggregations Using Pivoting**

One technique for solving custom aggregate problems is pivoting. You pivot the values that need to participate in the aggregate calculation; when they all appear in the same result row, you perform the calculation as a linear one across the columns. With a large number of elements you’ll end up with very lengthy query strings; therefore, this pivoting technique is limited to situations where each group has a small number of elements. Note that unless you have a sequencing column within the group, you need to calculate row numbers that will be used to identify the position of elements within the group. For example, if you need to concatenate all values from the string column per group, what do you specify as the pivoted attribute list (the spreading values)? The values in the memberid column are not known ahead of time, plus they differ in each group. Row numbers representing positions within the group solve this problem.
String Concatenation Using Pivoting

As the first example, the following query calculates an aggregate string concatenation over the column string for each group with a pivoting technique:

```sql
SELECT groupid,

[1] + COALESCE(',' + [2], '')
+ COALESCE(',' + [3], '')
+ COALESCE(',' + [4], '') AS string
FROM (SELECT groupid, string,

    ROW_NUMBER() OVER(PARTITION BY groupid ORDER BY memberid) AS rn
FROM dbo.Groups AS A) AS D
PIVOT(MAX(string) FOR rn IN([1],[2],[3],[4])) AS P;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>string</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>stra1,stra2</td>
</tr>
<tr>
<td>b</td>
<td>strb1,strb2,strb3,strb4</td>
</tr>
<tr>
<td>c</td>
<td>strc1,strc2,strc3</td>
</tr>
</tbody>
</table>

The query that generates the derived table D calculates a row number within the group based on `memberid` order. The outer query pivots the values based on the row numbers, and it performs linear concatenation. I'm assuming here that each group has at most four rows, so I specified four row numbers. You need as many row numbers as the maximum number of elements you anticipate.

The `COALESCE` function is used to replace a NULL representing a nonexistent element with an empty string so as not to cause the result to become NULL. You don't need the `COALESCE` function with the first element ([1]) because at least one element must exist in the group; otherwise, the group won't appear in the table.

Aggregate Product Using Pivoting

In a similar manner, you can calculate the product of the values in the `val` column for each group:

```sql
SELECT groupid,

[1] * COALESCE([2], 1)
* COALESCE([3], 1)
* COALESCE([4], 1) AS product
FROM (SELECT groupid, val,

    ROW_NUMBER() OVER(PARTITION BY groupid ORDER BY memberid) AS rn
FROM dbo.Groups AS A) AS D
PIVOT(MAX(val) FOR rn IN([1],[2],[3],[4])) AS P;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>product</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>42</td>
</tr>
<tr>
<td>b</td>
<td>693</td>
</tr>
<tr>
<td>c</td>
<td>960</td>
</tr>
</tbody>
</table>
The need for an aggregate product is common in financial applications—for example, to calculate compound interest rates.

User Defined Aggregates (UDA)

SQL Server allows you to create your own user-defined aggregates (UDAs). You write UDAs in a .NET language of your choice (for example, C# or Visual Basic), and you use them in T-SQL. This book is dedicated to T-SQL and not to the common language runtime (CLR), so I won’t explain CLR UDAs at great length. Rather, I’ll provide you with a couple of examples with step-by-step instructions and, of course, the T-SQL interfaces involved. Examples are provided in both C# and Visual Basic.

CLR Code in a Database

This section discusses .NET common language runtime (CLR) integration in SQL Server; therefore, it’s appropriate to spend a couple of words explaining the reasoning behind CLR integration in a database. It is also important to identify the scenarios where using CLR objects is more appropriate than using T-SQL.

Developing in .NET languages such as C# and Visual Basic gives you an incredibly rich programming model. The .NET Framework includes literally thousands of prepared classes, and it is up to you to make astute use of them. .NET languages are not just data oriented like SQL, so you are not as limited. For example, regular expressions are extremely useful for validating data, and they are fully supported in .NET. SQL languages are set oriented and slow to perform row-oriented (row-by-row or one-row-at-a-time) operations. Sometimes you need row-oriented operations inside the database; moving away from cursors to CLR code should improve the performance. Another benefit of CLR code is that it can be much faster than T-SQL code for operations such as string manipulation and iterations and in computationally intensive calculations.

SQL Server 2005 introduced CLR integration, and SQL Server 2008 enhances this integration in a number of ways. Later in this section I’ll describe the enhancements that are applicable to UDAs. Although SQL Server supported programmatic extensions even before CLR integration was introduced, CLR integration in .NET code is superior in a number of ways.

For example, you could add functionality to earlier versions of SQL Server (before 2005) using extended stored procedures. However, such procedures can compromise the integrity of SQL Server processes because their memory and thread management is not integrated well enough with SQL Server’s resource management. .NET code is managed by the CLR inside SQL Server, and because the CLR itself is managed by SQL Server, it is much safer to use than extended procedure code.
T-SQL—a set-oriented language—was designed to deal mainly with data and is optimized for data manipulation. You should not rush to translate all your T-SQL code to CLR code. T-SQL is still SQL Server's primary language. Data access can be achieved through T-SQL only. If an operation can be expressed as a set-oriented one, you should program it in T-SQL.

You need to make another important decision before you start using CLR code inside SQL Server. You need to decide where your CLR code is going to run—at the server or at the client. CLR code is typically faster and more flexible than T-SQL for computations, and thus it extends the opportunities for server-side computations. However, the server side is typically a single working box, and load balancing at the data tier is still in its infancy. Therefore, you should consider whether it would be more sensible to process those computations at the client side.

With CLR code, you can write stored procedures, triggers, user-defined functions, user-defined types, and user-defined aggregate functions. The last two objects can't be written with declarative T-SQL; rather, they can be written only with CLR code. A user-defined type (UDT) is the most complex CLR object type and demands extensive coverage.

More Info For details about programming CLR UDTs, as well as programming CLR routines, please refer to *Inside Microsoft SQL Server 2008: T-SQL Programming*.

Let’s start with a concrete implementation of two UDAs. The steps involved in creating a CLR-based UDA are as follows:

1. Define the UDA as a class in a .NET language.
2. Compile the class you defined to build a CLR assembly.
3. Register the assembly in SQL Server using the CREATE ASSEMBLY command in T-SQL.
4. Use the CREATE AGGREGATE command in T-SQL to create the UDA that references the registered assembly.

Note You can register an assembly and create a CLR object from Microsoft Visual Studio 2008 directly, using the project deployment option (from the Build menu item, choose the Deploy option). Direct deployment from Visual Studio is supported only with the Professional edition or higher; if you're using the Standard edition, your only option is explicit deployment in SQL Server.

This section will provide examples for creating aggregate string concatenation and aggregate product functions in both C# and Visual Basic. You can find the code for the C# classes in Listing 8-2 and the code for the Visual Basic classes in Listing 8-3. You’ll be provided with the requirements for a CLR UDA alongside the development of a UDA.
LISTING 8-2 C# code for UDAs

```csharp

Creating and Deploying an Assembly in Visual Studio 2008

1. In Visual Studio 2008, create a new C# or Visual Basic project based on your language preference. Use the Database folder and the SQL Server Project template.

   **Note** This template is not available in Visual Studio 2008, Standard edition. If you’re working with the Standard edition, use the Class Library template and manually write all the code.

2. In the New Project dialog box, specify the following information:
   - Name  UDAs
   - Location  C:\
   - Solution Name  UDAs

   When you’re done entering the information, confirm that it is correct.

3. At this point, you’ll be requested to specify a database reference. Create a new database reference to the tempdb database in the SQL Server instance you’re working with and choose it. The database reference you choose tells Visual Studio where to deploy the UDAs that you develop.

4. After confirming the choice of database reference, in the Solution Explorer window, right-click the UDAs project, select the menu items Add and Aggregate, and then choose the Aggregate template. If you’re using C#, rename the class Aggregate1.cs to UDAClasses.cs. If you’re using Visual Basic, rename Aggregate1.vb to UDAClasses.vb. Confirm.

5. Examine the code of the template. You’ll find that a UDA is implemented as a structure (struct in C#, Structure in Visual Basic). It can be implemented as a class as well. The first block of code in the template includes namespaces that are used in the assembly (lines of code starting with using in C# and with Imports in Visual Basic). Add three more statements to include the following namespaces: System.Text, System.IO, and System.Runtime.InteropServices. (You can copy those from Listing 8-2 or Listing 8-3.) You’ll use the StringBuilder class from the System.Text namespace, the BinaryReader and BinaryWriter classes from the System.IO namespace, and the StructLayout attribute from the System.Runtime.InteropServices namespace (in the second UDA).

6. Rename the default name of the UDA—which is currently the same name as the name of the class (UDAClasses)—to StringConcat.

7. You’ll find four methods that are already provided by the template. These are the methods that every UDA must implement. However, if you use the Class Library template for your
project, you have to write them manually. Using the Aggregate template, all you have to do is fill them with your code. Following is a description of the four methods:

- **Init**  This method is used to initialize the computation. It is invoked once for each group that the query processor is aggregating.

- **Accumulate**  The name of the method gives you a hint at its purpose—accumulating the aggregate values, of course. This method is invoked once for each value (that is, for every single row) in the group that is being aggregated. It uses input parameters, and the parameters have to be of the data types corresponding to the native SQL Server data types of the columns you are going to aggregate. The data type of the input can also be a CLR UDT. In SQL Server 2005, UDAs supported no more than one input parameter. In SQL Server 2008, UDAs support multiple input parameters.

- **Merge**  Notice that this method uses an input parameter with the type that is the aggregate class. The method is used to merge multiple partial computations of an aggregation.

- **Terminate**  This method finishes the aggregation and returns the result.

8. Add an internal (private) variable—`sb`—to the class just before the **Init** method. You can do so by simply copying the code that declares it from Listing 8-2 or Listing 8-3, depending on your choice of language. The variable `sb` is of type `StringBuilder` and will hold the intermediate aggregate value.

9. Override the current code for the four methods with the code implementing them from Listing 8-2 or Listing 8-3. Keep in mind the following points for each method:

- In the **Init** method, you initialize `sb` with an empty string.

- The **Accumulate** method accepts two input parameters (new in SQL Server 2008)—`v` and `separator`. The parameter `v` represents the value to be concatenated, and the parameter `separator` is obviously the separator. If `v` is NULL, it is simply ignored, similar to the way built-in aggregates handle NULLs. If `v` is not NULL, the value in `v` and a separator are appended to `sb`.

- In the **Merge** method, you are simply adding a partial aggregation to the current one. You do so by calling the **Accumulate** method of the current aggregation and adding the termination (final value) of the other partial aggregation. The input of the Merge function refers to the class name, which you revised earlier to `StringConcat`.

- The **Terminate** method is very simple as well; it just returns the string representation of the aggregated value minus the superfluous separator at the end.

10. Delete the last two rows of the code in the class from the template; these are a placeholder for a member field. You already defined the member field you need at the beginning of the UDA.
11. Next, go back to the top of the UDA, right after the inclusion of the namespaces. You'll find attribute names that you want to include. Attributes help Visual Studio in deployment, and they help SQL Server to optimize the usage of the UDA. UDAs have to include the Serializable attribute. Serialization in .NET means saving the values of the fields of a class persistently. UDAs need serialization for intermediate results. The format of the serialization can be native, meaning they are left to SQL Server or defined by the user. Serialization can be native if you use only .NET value types; it has to be user defined if you use .NET reference types. Unfortunately, the string type is a reference type in .NET. Therefore, you have to prepare your own serialization. You have to implement the IBinarySerialize interface, which defines just two methods: Read and Write. The implementation of these methods in our UDA is very simple. The Read method uses the ReadString method of the StringBuilder class. The Write method uses the default ToString method. The ToString method is inherited by all .NET classes from the topmost class, called System.Object.

Continue implementing the UDA by following these steps:

11.1. Specify that you are going to implement the IBinarySerialize interface in the structure. If you're using C#, you do so by adding a colon and the name of the interface right after the name of the structure (the UDA name). If you're using Visual Basic, you do so by adding Implements IBinarySerialize after the name of the structure.

11.2. Copy the Read and Write methods from Listing 8-2 or Listing 8-3 to the end of your UDA.

11.3. Change the Format.Native property of the SqlUserDefinedAggregate attribute to Format.UserDefined. In SQL Server 2005, with user-defined serialization, your aggregate was limited to 8,000 bytes only. You had to specify how many bytes your UDA could return at maximum with the MaxByteSize property of the SqlUserDefinedAggregate attribute. SQL Server 2008 lifts this restriction and supports unlimited size (or more accurately, the maximum size supported by large object types like VARCHAR(MAX), which is currently 2 GB). A value of –1 in the MaxByteSize property indicates unlimited size.

12. You’ll find some other interesting properties of the SqlUserDefinedAggregate attribute in Listings 8-2 and 8-3. Let’s explore them:

- **IsInvariantToDuplicates** This is an optional property. For example, the MAX aggregate is invariant to duplicates, while SUM is not.
- **IsInvariantToNulls** This is another optional property. It specifies whether the aggregate is invariant to NULLs.
- **IsInvariantToOrder** This property is reserved for future use. It is currently ignored by the query processor. Therefore, order is currently not guaranteed. If you want to concatenate elements in a certain order, you have to implement your own sorting logic either in the Accumulate or the Terminate methods. This naturally incurs extra cost and unfortunately cannot benefit from index ordering.
- **IsNullIfEmpty**  This property indicates whether the aggregate returns a NULL if no values have been accumulated.

13. Add the aforementioned properties to your UDA by copying them from Listing 8-2 or Listing 8-3. Your first UDA is now complete!

14. Listings 8-2 and 8-3 also have the code to implement a product UDA (*Product*). Copy the complete code implementing *Product* to your script. Note that this UDA involves handling of big integers only. Because the UDA internally deals only with value types, it can use native serialization. Native serialization requires that the `StructLayoutAttribute` be specified as `StructLayout.LayoutKind.Sequential` if the UDA is defined in a class and not a structure. Otherwise, the UDA implements the same four methods as your previous UDA. An additional check in the *Accumulate* method prevents out-of-range values.

15. Save all files by choosing the File menu item and then choosing Save All.

16. Create the assembly file in the project folder by building the solution. You do this by choosing the Build menu item and then choosing Build Solution.

17. Deploy the assembly in SQL Server.

**Note**  To automatically deploy the solution in SQL Server, you normally choose the Build menu item and then choose Deploy Solution. However, at the time of this writing, automatic deployment in Visual Studio 2008 with Service Pack 1 fails if you use any of the new UDA features in SQL Server 2008 (multiple input parameters or the unlimited maximum size). Therefore, I’ll provide instructions here to do explicit deployment.

18. Explicit deployment of the UDAs in SQL Server involves running the CREATE ASSEMBLY command to import the intermediate language code from the assembly file into the target database (tempdb in our case) and the CREATE AGGREGATE command to register each aggregate. If you used C# to define the UDAs, run the following code while connected to the tempdb database:

```sql
CREATE ASSEMBLY UDAs
FROM 'C:\UDAs\UDAs\bin\Debug\UDAs.dll';

CREATE AGGREGATE dbo.StringConcat
(
  @value   AS NVARCHAR(MAX),
  @separator AS NCHAR(1)
)
RETURNS NVARCHAR(MAX)
EXTERNAL NAME UDAs.StringConcat;

CREATE AGGREGATE dbo.Product
(
  @value   AS BIGINT
)
RETURNS BIGINT
EXTERNAL NAME UDAs.Product;
```
If you used Visual Basic, run the following code:

```sql
CREATE ASSEMBLY UDAs
  FROM 'C:\UDAs\UDAs\bin\UDAs.dll';

CREATE AGGREGATE dbo.StringConcat
  (  
    @value     AS NVARCHAR(MAX),
    @separator AS NCHAR(1)
  )
  RETURNS NVARCHAR(MAX)
  EXTERNAL NAME UDAs.[UDAs.StringConcat];

CREATE AGGREGATE dbo.Product
  (  
    @value     AS BIGINT
  )
  RETURNS BIGINT
  EXTERNAL NAME UDAs.[UDAs.Product];
```

The assembly should be cataloged at this point, and both UDAs should be created.

You can check whether the deployment was successful by browsing the `sys.assemblies` and `sys.assembly_modules` catalog views, which are in the tempdb database in our case. Run the following code to query those views:

```sql
SELECT * FROM sys.assemblies;
SELECT * FROM sys.assembly_modules;
```

Note that to run user-defined assemblies in SQL Server, you need to enable the server configuration option `clr enabled` (which is disabled by default). You do so by running the following code:

```sql
EXEC sp_configure 'clr enabled', 1;
RECONFIGURE WITH OVERRIDE;
```

This requirement is applicable only if you want to run user-defined assemblies; this option is not required to be turned on if you want to run system-supplied assemblies.

That's basically it. You use UDAs just like you use any built-in aggregate function—and that's one of their great advantages compared to other solutions to custom aggregates. To test the new functions, run the following code, and you'll get the same results returned by the other solutions to custom aggregates I presented earlier:

```sql
SELECT groupid, dbo.StringConcat(string, N',') AS string
FROM dbo.Groups
GROUP BY groupid;

SELECT groupid, dbo.Product(val) AS product
FROM dbo.Groups
GROUP BY groupid;
```
Note that the `StringConcat` function expects a non-NULL separator as input and will fail if provided with a NULL. Of course, you can add logic to the function’s definition to use some default separator when a NULL is specified.

**Specialized Solutions**

Another type of solution for custom aggregates is developing a specialized, optimized solution for each aggregate. The advantage is usually the improved performance of the solution. The disadvantage is that you probably won’t be able to use similar logic for other aggregate calculations.

**Specialized Solution for Aggregate String Concatenation**

A specialized solution for aggregate string concatenation uses the PATH mode of the FOR XML query option. This beautiful (and extremely fast) technique was devised by Michael Rys, a program manager with the Microsoft SQL Server development team, and Eugene Kogan, a technical lead on the Microsoft SQL Server Engine team. The PATH mode provides an easier way to mix elements and attributes than the EXPLICIT directive. Here’s the specialized solution for aggregate string concatenation:

```
SELECT groupid,
       STUFF((SELECT ',' + string AS [text()]
             FROM dbo.Groups AS G2
             WHERE G2.groupid = G1.groupid
             ORDER BY memberid
             FOR XML PATH('')), 1, 1, '') AS string
FROM dbo.Groups AS G1
GROUP BY groupid;
```

The subquery basically returns an ordered path of all strings within the current group. Because an empty string is provided to the PATH clause as input, a wrapper element is not generated. An expression with no alias (for example, `' + string`) or one aliased as `[text()]` is inlined, and its contents are inserted as a text node. The purpose of the STUFF function is simply to remove the first comma (by substituting it with an empty string).

**Dynamic Pivoting**

Now that you are familiar with a fast, specialized solution to string concatenation, you can put it to use to achieve dynamic pivoting. Recall from the “Pivoting” section that the static solutions for pivoting in SQL Server require you to explicitly list the spreading values (the values in the spreading element). Consider the following static query, which I covered earlier in the “Pivoting” section:

```
SELECT *
FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
       FROM dbo.Orders) AS D
PIVOT(SUM(qty) FOR orderyear IN([2006],[2007],[2008])) AS P;
```
Note that this query is against the dbo.Orders table that you created and populated earlier by running the code in Listing 8-1. Here you have to explicitly list the order years in the IN clause. If you want to make this solution more dynamic, query the distinct order years from the table and use the FOR XML PATH technique to construct the comma-separated list of years. You can use the QUOTENAME function to convert the integer years to Unicode character strings and add brackets around them. Also, using QUOTENAME is critical to prevent SQL Injection if this technique is used for a nonnumeric spreading column. The query that produces the comma-separated list of years looks like this:

```sql
SELECT
    STUFF(
        (SELECT N',' + QUOTENAME(orderyear) AS [text()]
         FROM (SELECT DISTINCT YEAR(orderdate) AS orderyear
              FROM dbo.Orders) AS Years
         ORDER BY orderyear
         FOR XML PATH('')), 1, 1, '');
```

Note that this useful technique has some limitations, though not serious ones, because it's XML based. For example, characters that have special meaning in XML, like '<', will be converted to codes (like &lt;), yielding the wrong pivot statement.

What's left is to construct the whole query string, store it in a variable and use the `sp_executesql` stored procedure to execute it dynamically, like so:

```sql
DECLARE @sql AS NVARCHAR(1000);
SET @sql = N'SELECT *
    FROM (SELECT custid, YEAR(orderdate) AS orderyear, qty
         FROM dbo.Orders) AS D
    PIVOT(SUM(qty) FOR orderyear IN(' +
    STUFF(
        (SELECT N',' + QUOTENAME(orderyear) AS [text()]
         FROM (SELECT DISTINCT YEAR(orderdate) AS orderyear
              FROM dbo.Orders) AS Years
         ORDER BY orderyear
         FOR XML PATH('')), 1, 1, '') + N')) AS P;';
EXEC sp_executesql @stmt = @sql;
```

**Specialized Solution for Aggregate Product**

Keep in mind that to calculate an aggregate product, you have to scan all values in the group. So the performance potential your solution can reach is to achieve the calculation by scanning the data only once, using a set-based query. In the case of an aggregate product, this can be achieved using mathematical manipulation based on logarithms. I'll rely on the following logarithmic equations:

*Equation 1*: \( \log_a(b) = x \) if and only if \( a^x = b \)
Equation 2: $\log_a(v_1 \times v_2 \times \ldots \times v_n) = \log_a(v_1) + \log_a(v_2) + \ldots + \log_a(v_n)$

Basically, what you’re going to do here is a transformation of calculations. You have support in T-SQL for the LOG, POWER, and SUM functions. Using those, you can generate the missing product. Group the data by the groupid column, as you would with any built-in aggregate. The expression $\text{SUM}($LOG10(val)$)$ corresponds to the right side of Equation 2, where the base $a$ is equal to 10 in our case, because you used the LOG10 function. To get the product of the elements, all you have left to do is raise the base (10) to the power of the right side of the equation. In other words, the expression $\text{POWER}(10., \text{SUM}(\text{LOG10}(\text{val})))$ gives you the product of elements within the group. Here’s what the full query looks like:

```
SELECT groupid, POWER(10., SUM(LOG10(val))) AS product
FROM dbo.Groups
GROUP BY groupid;
```

This is the final solution if you’re dealing only with positive values. However, the logarithm function is undefined for zero and negative numbers. You can use pivoting techniques to identify and deal with zeros and negatives as follows:

```
SELECT groupid,
    CASE
        WHEN MAX(CASE WHEN val = 0 THEN 1 END) = 1 THEN 0
        ELSE CASE WHEN COUNT(CASE WHEN val < 0 THEN 1 END) % 2 = 0
            THEN 1 ELSE -1
        END * POWER(10., SUM(LOG10(NULLIF(ABS(val), 0))))
    END AS product
FROM dbo.Groups
GROUP BY groupid;
```

The outer CASE expression first uses a pivoting technique to check whether a 0 value appears in the group, in which case it returns a 0 as the result. The ELSE clause invokes another CASE expression, which also uses a pivoting technique to count the number of negative values in the group. If that number is even, it produces a +1; if it’s odd, it produces a –1. The purpose of this calculation is to determine the numerical sign of the result. The sign (–1 or +1) is then multiplied by the product of the absolute values of the numbers in the group to give the desired product.

Note that NULLIF is used here to substitute zeros with NULLs. You might expect this part of the expression not to be evaluated at all if a zero is found. But remember that the optimizer can consider many different physical plans to execute your query. As a result, you can’t be certain of the actual order in which parts of an expression will be evaluated. By substituting zeros with NULLs, you ensure that you’ll never get a domain error if the LOG10 function ends up being invoked with a zero as an input. This use of NULLIF, together with the use of ABS, allows this solution to accommodate inputs of any sign (negative, zero, and positive).
You could also use a pure mathematical approach to handle zeros and negative values using the following query:

```sql
SELECT groupid,
       CAST(ROUND(EXP(SUM(LOG(ABS(NULLIF(val,0))))) * (1-SUM(1-SIGN(val))%4) * (1-SUM(1-SQUARE(SIGN(val)))) , 0) AS INT)
AS product
FROM dbo.Groups
GROUP BY groupid;
```

This example shows that you should never lose hope when searching for an efficient solution. If you invest the time and think outside the box, in most cases you’ll find a solution.

**Specialized Solutions for Aggregate Bitwise Operations**

In this section, I’ll introduce specialized solutions for aggregating the T-SQL bitwise operations—bitwise OR (|), bitwise AND (&), and bitwise XOR (^). I’ll assume that you’re familiar with the basics of bitwise operators and their uses and provide only a brief overview. If you’re not, please refer first to the section “Bitwise Operators” in SQL Server Books Online.

Bitwise operations are operations performed on the individual bits of integer data. Each bit has two possible values, 1 and 0. Integers can be used to store bitmaps, or strings of bits, and in fact they are used internally by SQL Server to store metadata information—for example, properties of indexes (clustered, unique, and so on) and properties of databases (readonly, restrict access, autoshrink, and so on). You might also choose to store bitmaps yourself to represent sets of binary attributes—for example, a set of permissions where each bit represents a different permission.

Some experts advise against using such a design because it violates 1NF (first normal form, which requires attributes to be atomic). You might well prefer to design your data in a more normalized form, where attributes like this are stored in separate columns. I don’t want to get into a debate about which design is better. Here I’ll assume a given design that does store bitmaps with sets of flags, and I’ll assume that you need to perform aggregate bitwise activities on these bitmaps. I just want to introduce the techniques for cases where you do find the need to use them.

Bitwise OR (|) is usually used to construct bitmaps or to generate a result bitmap that accumulates all bits that are turned on. In the result of bitwise OR, bits are turned on (that is, have value 1) if they are turned on in at least one of the separate bitmaps.

Bitwise AND (&) is usually used to check whether a certain bit (or a set of bits) is turned on by ANDing the source bitmap and a mask. It’s also used to accumulate only bits that are turned on in all bitmaps. It generates a result bit that is turned on if that bit is turned on in all the individual bitmaps.

Bitwise XOR (^) is usually used to calculate parity or as part of a scheme to encrypt data. For each bit position, the result bit is turned on if it is on in an odd number of the individual bitmaps.
Chapter 8  Aggregating and Pivoting Data

Note  Bitwise XOR is the only bitwise operator that is reversible. That's why it's used for parity calculations and encryption.

Aggregate versions of the bitwise operators are not provided in SQL Server, and I'll provide solutions here to perform aggregate bitwise operations. I'll use the same Groups table that I used in my other custom aggregate examples. Assume that the integer column \textit{val} represents a bitmap. To see the bit representation of each integer, first create the function \texttt{DecToBase} by running the following code:

\begin{verbatim}
IF OBJECT_ID('dbo.DecToBase') IS NOT NULL
    DROP FUNCTION dbo.DecToBase;
GO
CREATE FUNCTION dbo.DecToBase(@val AS BIGINT, @base AS INT)
    RETURNS VARCHAR(63)
AS
BEGIN
    DECLARE @r AS VARCHAR(63), @alldigits AS VARCHAR(36);
    SET @alldigits = '0123456789ABCDEFGHIJKLMNOPQRSTUVWXYZ';
    SET @r = '';
    WHILE @val > 0
    BEGIN
        SET @r = SUBSTRING(@alldigits, @val % @base + 1, 1) + @r;
        SET @val = @val / @base;
    END
    RETURN @r;
END
GO
\end{verbatim}

The function accepts two inputs: a 64-bit integer holding the source bitmap and a base in which you want to represent the data. Use the following query to return the bit representation of the integers in the \textit{val} column of Groups:

\begin{verbatim}
SELECT groupid, val,
    RIGHT(REPLICATE('0', 32) + CAST(dbo.DecToBase(val, 2) AS VARCHAR(64)),
        32) AS binval
FROM dbo.Groups;
\end{verbatim}

This code generates the following output (only the 10 rightmost digits of \textit{binval} are shown):

\begin{verbatim}
groupid | val  | binval            
---------|------|-------------------
     a    |  6   | 00000110          
     a    |  7   | 00000111          
     b    |  3   | 00000011          
     b    |  7   | 00000111          
     b    |  3   | 00000011          
     b    |  11  | 00001011          
     c    |  8   | 00001000          
     c    |  10  | 00001010          
     c    |  12  | 00001100          
\end{verbatim}
The binval column shows the val column in base 2 representation, with leading zeros to create a string with a fixed number of digits. Of course, you can adjust the number of leading zeros according to your needs, which I did to produce the outputs I’ll show. To avoid distracting you from the techniques I want to focus on, however, the code for that adjustment is not in my code samples.

**Aggregate Bitwise OR**  Without further ado, let’s start with calculating an aggregate bitwise OR. To give tangible context to the problem, imagine that you’re maintaining application security in the database. The groupid column represents a user, and the val column represents a bitmap with permission states (either 1 for granted or 0 for not granted) of a role the user is a member of. You’re after the effective permissions bitmap for each user (group), which should be calculated as the aggregate bitwise OR between all bitmaps of roles the user is a member of.

The main aspect of a bitwise OR operation that I’ll rely on in my solutions is the fact that it’s equivalent to the arithmetic sum of the values represented by each distinct bit value that is turned on in the individual bitmaps. Within an integer, a bit represents the value \(2^{(bit \_pos-1)}\). For example, the bit value of the third bit is \(2^2 = 4\). Take, for example, the bitmaps for user c: 8 (1000), 10 (1010), and 12 (1100). The bitmap 8 has only one bit turned on—the bit value representing 8; 10 has the bits representing 8 and 2 turned on; and 12 has the 8 and 4 bits turned on. The distinct bits turned on in any of the integers 8, 10, and 12 are the 2, 4, and 8 bits, so the aggregate bitwise OR of 8, 10, and 12 is equal to \(2 + 4 + 8 = 14\) (1110).

The following solution relies on the aforementioned logic by extracting the individual bit values that are turned on in any of the participating bitmaps. The extraction is achieved using the expression \(MAX(val \& <bitval>)\). The query then performs an arithmetic sum of the individual bit values:

```sql
SELECT groupid,
       MAX(val & 1)
       + MAX(val & 2)
       + MAX(val & 4)
       + MAX(val & 8)
       + MAX(val & 1073741824) AS agg_or
FROM dbo.Groups
GROUP BY groupid;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>agg_or</th>
<th>binval</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>7</td>
<td>00000111</td>
</tr>
<tr>
<td>b</td>
<td>15</td>
<td>00001111</td>
</tr>
<tr>
<td>c</td>
<td>14</td>
<td>00001110</td>
</tr>
</tbody>
</table>

Note that I added a third column (binval) to the output showing the 10 rightmost digits of the binary representation of the result value. I’ll continue to do so with the rest of the queries that apply aggregate bitwise operations.
Similarly, you can use $\text{SUM(DISTINCT val} \& <\text{bitval}>)$ instead of $\text{MAX(val} \& <\text{bitval}>)$ because the only possible results are $<\text{bitval}>$ and $0$:

```sql
SELECT groupid,
    SUM(DISTINCT val & 1)
  + SUM(DISTINCT val & 2)
  + SUM(DISTINCT val & 4)
  + SUM(DISTINCT val & 8)
  -- ...
  + SUM(DISTINCT val & 1073741824) AS agg_or
FROM dbo.Groups
GROUP BY groupid;
```

Both solutions suffer from the same limitation—lengthy query strings—because of the need for a different expression for each bit value. In an effort to shorten the query strings, you can use an auxiliary table. You join the Groups table with an auxiliary table that contains all relevant bit values, using $\text{val} \& \text{bitval} = \text{bitval}$ as the join condition. The result of the join will include all bit values that are turned on in any of the bitmaps. You can then find $\text{SUM(DISTINCT <bitval>)}$ for each group. You can easily generate the auxiliary table of bit values from the Nums table used earlier. Filter as many numbers as the bits that you might need and raise $2$ to the power $n-1$. Here’s the complete solution:

```sql
SELECT groupid, SUM(DISTINCT bitval) AS agg_or
FROM dbo.Groups
JOIN (SELECT POWER(2, n-1) AS bitval
    FROM dbo.Nums
    WHERE n <= 31) AS Bits
ON val & bitval = bitval
GROUP BY groupid;
```

**Aggregate Bitwise AND**  In a similar manner, you can calculate an aggregate bitwise AND. In the permissions scenario, an aggregate bitwise AND represents the most restrictive permission set. Just keep in mind that a bit value should be added to the arithmetic sum only if it’s turned on in all bitmaps. So first group the data by $\text{groupid}$ and $\text{bitval}$ and filter only the groups where $\text{MIN(val} \& \text{bitval}) > 0$, meaning that the bit value was turned on in all bitmaps. In an outer query, group the data by $\text{groupid}$ and perform the arithmetic sum of the bit values from the inner query:

```sql
SELECT groupid, SUM(bitval) AS agg_and
FROM (SELECT groupid, bitval
    FROM dbo.Groups,
    (SELECT POWER(2, n-1) AS bitval
        FROM dbo.Nums
        WHERE n <= 31) AS Bits
    ON val & bitval = bitval
    GROUP BY groupid, bitval
    HAVING MIN(val & bitval) > 0) AS D
GROUP BY groupid;
```
This query generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>agg_and</th>
<th>binval</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>6</td>
<td>00000110</td>
</tr>
<tr>
<td>b</td>
<td>3</td>
<td>00000011</td>
</tr>
<tr>
<td>c</td>
<td>8</td>
<td>00001000</td>
</tr>
</tbody>
</table>

**Aggregate Bitwise XOR**  
To calculate an aggregate bitwise XOR operation, filter only the `groupid, bitval` groups that have an odd number of bits turned on, as shown in the following code, which illustrates an aggregate bitwise XOR using Nums:

```sql
SELECT groupid, SUM(bitval) AS agg_xor
FROM (SELECT groupid, bitval
      FROM dbo.Groups,
      (SELECT POWER(2, n-1) AS bitval
       FROM dbo.Nums
       WHERE n <= 31) AS Bits
      GROUP BY groupid, bitval
      HAVING SUM(SIGN(val & bitval)) % 2 = 1) AS D
GROUP BY groupid;
```

This query produces the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>agg_xor</th>
<th>binval</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>1</td>
<td>00000001</td>
</tr>
<tr>
<td>b</td>
<td>12</td>
<td>00001100</td>
</tr>
<tr>
<td>c</td>
<td>14</td>
<td>00001110</td>
</tr>
</tbody>
</table>

**Median**

As another example of a specialized custom aggregate solution, I’ll use the statistical median calculation. Suppose that you need to calculate the median of the `val` column for each group. There are two different definitions of median. Here we will return the middle value in case we have an odd number of elements and the average of the two middle values in case we have an even number of elements.

The following code shows a technique for calculating the median:

```sql
WITH Tiles AS
  (SELECT groupid, val,
   NTILE(2) OVER(PARTITION BY groupid ORDER BY val) AS tile
   FROM dbo.Groups
  ),
GroupedTiles AS
  (SELECT groupid, tile, COUNT(*) AS cnt,
   CASE WHEN tile = 1 THEN MAX(val) ELSE MIN(val) END AS val
   FROM Tiles
   GROUP BY groupid, tile
  )
```
SELECT groupid,  
CASE WHEN MIN(cnt) = MAX(cnt) THEN AVG(1.*val)  
ELSE MIN(val) END AS median  
FROM GroupedTiles  
GROUP BY groupid;

This code generates the following output:

<table>
<thead>
<tr>
<th>groupid</th>
<th>median</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>6.500000</td>
</tr>
<tr>
<td>b</td>
<td>5.000000</td>
</tr>
<tr>
<td>c</td>
<td>10.000000</td>
</tr>
</tbody>
</table>

The Tiles CTE calculates the NTILE(2) value within the group, based on val order. When you have an even number of elements, the first half of the values gets tile number 1, and the second half gets tile number 2. In an even case, the median is supposed to be the average of the highest value within the first tile and the lowest in the second. When you have an odd number of elements, remember that an additional row is added to the first group. This means that the highest value in the first tile is the median.

The second CTE (GroupedTiles) groups the data by group and tile number, returning the row count for each group and tile as well as the val column, which for the first tile is the maximum value within the tile and for the second tile is the minimum value within the tile.

The outer query groups the two rows in each group (one representing each tile). A CASE expression in the SELECT list determines what to return based on the parity of the group’s row count. When the group has an even number of rows (that is, the group’s two tiles have the same row count), you get the average of the maximum in the first tile and the minimum in the second. When the group has an odd number of elements (that is, the group’s two tiles have different row counts), you get the minimum of the two values, which happens to be the maximum within the first tile, which, in turn, happens to be the median.

Using the ROW_NUMBER function, you can come up with additional solutions to finding the median that are more elegant and somewhat simpler. Here’s the first example:

WITH RN AS  
(  
SELECT groupid, val,  
ROW_NUMBER()  
OVER(PARTITION BY groupid ORDER BY val, memberid) AS rna,  
ROW_NUMBER()  
OVER(PARTITION BY groupid ORDER BY val DESC, memberid DESC) AS rnd  
FROM dbo.Groups  
)  
SELECT groupid, AVG(1.*val) AS median  
FROM RN  
WHERE ABS(rna - rnd) <= 1  
GROUP BY groupid;
The idea is to calculate two row numbers for each row: one based on val, memberid (the tiebreaker) in ascending order (rna) and the other based on the same attributes in descending order (rnd). Two sequences sorted in opposite directions have an interesting mathematical relationship that you can use to your advantage. The absolute difference between the two is smaller than or equal to 1 only for the elements that need to participate in the median calculation. Take, for example, a group with an odd number of elements; \( \text{ABS}(rna - rnd) \) is equal to 0 only for the middle row. For all other rows, it is greater than 1. Given an even number of elements, the difference is 1 for the two middle rows and greater than 1 for all others.

The reason for using memberid as a tiebreaker is to guarantee determinism of the row number calculations. Because you're calculating two different row numbers, you want to make sure that a value that appears at the \( n \)th position from the beginning in ascending order appears at the \( n \)th position from the end in descending order.

Once the values that need to participate in the median calculation are isolated, you just need to group them by groupid and calculate the average per group.

You can avoid the need to calculate two separate row numbers by deriving the second from the first. The descending row numbers can be calculated by subtracting the ascending row numbers from the count of rows in the group and adding one. For example, in a group of four elements, the row that got an ascending row number 1 would get the descending row number \( 4-1+1 = 4 \). Ascending row number 2 would get the descending row number \( 4-2+1 = 3 \) and so on. Deriving the descending row number from the ascending one eliminates the need for a tiebreaker. You're not dealing with two separate calculations; therefore, nondeterminism is not an issue anymore.

So the calculation \( rna - rnd \) becomes the following: \( rna - (cnt-rna+1) = 2*rn - cnt - 1 \). Here's a query that implements this logic:

```
WITH RN AS
  (SELECT groupid, val,
   ROW_NUMBER() OVER(PARTITION BY groupid ORDER BY val) AS rn,
   COUNT(*) OVER(PARTITION BY groupid) AS cnt
    FROM dbo.Groups
  )
SELECT groupid, AVG(1.*val) AS median
FROM RN
WHERE ABS(2*rn - cnt - 1) <= 1
GROUP BY groupid;
```

Here's another way to figure out which rows participate in the median calculation based on the row number and the count of rows in the group: \( rn IN((cnt+1)/2, (cnt+2)/2) \). For an odd number of elements, both expressions yield the middle row number. For example, if you have 7 rows, both \( (7+1)/2 \) and \( (7+2)/2 \) equal 4. For an even number of elements, the first expression yields the row number just before the middle point, and the second yields the
row number just after it. If you have 8 rows, \((8+1)/2\) yields 4, and \((8+2)/2\) yields 5. Here’s the query that implements this logic:

```
WITH RN AS
(
    SELECT groupid, val,
        ROW_NUMBER() OVER(PARTITION BY groupid ORDER BY val) AS rn,
        COUNT(*) OVER(PARTITION BY groupid) AS cnt
    FROM dbo.Groups
)
SELECT groupid, AVG(1.*val) AS median
FROM RN
WHERE rn IN((cnt+1)/2, (cnt+2)/2)
GROUP BY groupid;
```

**Mode**

The last specialized solution of a custom aggregate that I’ll cover is for the mode of a distribution. The mode is the most frequently occurring value. As an example of mode calculation, consider a request to return for each customer the ID of the employee who handled the most orders for that customer, according to the Sales.Orders table in the InsideTSQL2008 database. In case of ties, you need to determine what you want to do. One option is to return all tied employees; another option is to use a tiebreaker to determine which to return—for example, the one with the higher employee ID.

The first solution that I’ll present is based on ranking calculations. I’ll first describe a solution that applies a tiebreaker, and then I’ll explain the required revisions for the solution to return all ties.

You group the rows by customer ID and employee ID. You calculate a count of orders per group, plus a row number partitioned by customer ID, based on the order of count descending and employee ID descending. The rows with the employee ID that is the mode—with the higher employee ID used as a tiebreaker—have row number 1. What’s left is to define a table expression based on the query and in the outer query filter only the rows where the row number is equal to 1, like so:

```
USE InsideTSQL2008;

WITH C AS
(
    SELECT custid, empid, COUNT(*) AS cnt,
        ROW_NUMBER() OVER(PARTITION BY custid ORDER BY COUNT(*) DESC, empid DESC) AS rn
    FROM Sales.Orders
    GROUP BY custid, empid
)
SELECT custid, empid, cnt
FROM C
WHERE rn = 1;
```
This query generates the following output, shown here in abbreviated form:

<table>
<thead>
<tr>
<th>custid</th>
<th>empid</th>
<th>cnt</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>2</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>5</td>
<td>3</td>
<td>6</td>
</tr>
<tr>
<td>6</td>
<td>9</td>
<td>3</td>
</tr>
<tr>
<td>7</td>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>8</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>9</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>10</td>
<td>3</td>
<td>4</td>
</tr>
<tr>
<td>11</td>
<td>6</td>
<td>2</td>
</tr>
<tr>
<td>12</td>
<td>8</td>
<td>2</td>
</tr>
</tbody>
</table>

If you want to return all ties, simply use the RANK function instead of ROW_NUMBER and calculate it based on count ordering alone (without the employee ID tiebreaker), like so:

```
WITH C AS
    (
      SELECT custid, empid, COUNT(*) AS cnt,
             RANK() OVER(PARTITION BY custid
                          ORDER BY COUNT(*) DESC) AS rn
      FROM Sales.Orders
      GROUP BY custid, empid
    )

SELECT custid, empid, cnt
FROM C
WHERE rn = 1;
```

This time, as you can see in the following output, ties are returned:

<table>
<thead>
<tr>
<th>custid</th>
<th>empid</th>
<th>cnt</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>1</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>2</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>4</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>5</td>
<td>3</td>
<td>6</td>
</tr>
<tr>
<td>6</td>
<td>9</td>
<td>3</td>
</tr>
<tr>
<td>7</td>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>8</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>9</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>10</td>
<td>3</td>
<td>4</td>
</tr>
<tr>
<td>11</td>
<td>6</td>
<td>2</td>
</tr>
<tr>
<td>11</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>11</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>12</td>
<td>8</td>
<td>2</td>
</tr>
</tbody>
</table>

...
In case you do want to apply a tiebreaker, you can use another solution that is very efficient. It is based on the concatenation technique that I presented earlier in the chapter. Write a query that groups the data by customer ID and employee ID, and for each group, concatenate the count of rows and the employee ID to a single value (call it \( \text{binval} \)). Define a table expression based on this query. Have the outer query group the data by customer ID and calculate for each customer the maximum \( \text{binval} \). This maximum value contains the max count and within it the maximum employee ID. What's left is to extract the count and employee ID from the binary value by using the SUBSTRING function and convert the values to the original types. Here's the complete solution query:

```sql
SELECT custid,
       CAST(SUBSTRING(MAX(binval), 5, 4) AS INT) AS empid,
       CAST(SUBSTRING(MAX(binval), 1, 4) AS INT) AS cnt
FROM (SELECT custid,
            CAST(COUNT(*) AS BINARY(4)) + CAST(empid AS BINARY(4)) AS binval
       FROM Sales.Orders
       GROUP BY custid, empid) AS D
GROUP BY custid;
```

As an exercise, you can test the solutions against a table with a large number of rows. You will see that this solution is very fast.

**Histograms**

Histograms are powerful analytical tools that express the distribution of items. For example, suppose you need to figure out from the order information in the Sales.OrderValues view how many small, medium, and large orders you have, based on the order values. In other words, you need a histogram with three steps. The extreme values (the minimum and maximum values) are what defines values as small, medium, or large. Suppose for the sake of simplicity that the minimum order value is 10 and the maximum is 40. Take the difference between the two extremes (40 – 10 = 30) and divide it by the number of steps (3) to get the step size. In this case, it's 30 divided by 3, which is 10. So the boundaries of step 1 (small) would be 10 and 20; for step 2 (medium), they would be 20 and 30; and for step 3 (large), they would be 30 and 40.

To generalize this, let \( mn = \text{MIN}(val) \) and \( mx = \text{MAX}(val) \) and let \( \text{stepsize} = (mx – mn) / \@numsteps \). Given a step number \( n \), the lower bound of the step \( lb \) is \( mn + (n – 1) * \text{stepsize} \) and the higher bound \( hb \) is \( mn + n * \text{stepsize} \). Something is tricky here. What predicate do you use to bracket the elements that belong in a specific step? You can’t use \( \text{val BETWEEN lb and hb} \) because a value that is equal to \( hb \) appears in this step and also in the next step, where it equals the lower bound. Remember that the same calculation yielded the higher bound of one step and the lower bound of the next step. One approach to deal with this problem is to increase each of the lower bounds besides the first by one so that they exceed the previous step's higher bounds. With integers, this is a fine solution, but with another data type (such as NUMERIC in our case) it doesn’t work because there are potential values between adjacent steps but not within either one—between the cracks, so to speak.
What I like to do to solve the problem is keep the same value in both bounds, and instead of using BETWEEN, I use `val >= lb` and `val < hb`. This technique has its own issues, but I find it easier to deal with than the previous technique. The issue here is that the item with the highest quantity (40, in our simplified example) is left out of the histogram. To solve this, I add a very small number to the maximum value before calculating the step size: `stepsize = ((1E0*mx + 0.0000000001) – mn) / @numsteps`. This technique allows the item with the highest value to be included, and the effect on the histogram is otherwise negligible. I multiplied `mx` by the float value `1E0` to protect against the loss of the upper data point when `val` is typed as MONEY or SMALLMONEY.

So you need the following ingredients to generate the lower and higher bounds of the histogram’s steps: `@numsteps` (given as input), step number (the `n` column from the Nums auxiliary table), `mn`, and `stepsize`, which I described earlier.

Here’s the T-SQL code required to produce the step number, lower bound, and higher bound for each step of the histogram:

```sql
USE InsideTSQL2008;

DECLARE @numsteps AS INT;
SET @numsteps = 3;

SELECT n AS step,
    mn + (n - 1) * stepsize AS lb,
    mn + n * stepsize AS hb
FROM dbo.Nums
CROSS JOIN
    (SELECT MIN(val) AS mn,
        ((1E0*MAX(val) + 0.0000000001) - MIN(val))
        / @numsteps AS stepsize
    FROM Sales.OrderValues) AS D
WHERE n <= @numsteps;
```

This code generates the following output:

<table>
<thead>
<tr>
<th>step</th>
<th>lb</th>
<th>hb</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>12.5</td>
<td>5470.8333333337</td>
</tr>
<tr>
<td>2</td>
<td>5470.8333333337</td>
<td>10929.1666666667</td>
</tr>
<tr>
<td>3</td>
<td>10929.1666666667</td>
<td>16387.5000000001</td>
</tr>
</tbody>
</table>

You might want to encapsulate this code in a user-defined function to simplify the queries that return the actual histograms, like so:

```sql
IF OBJECT_ID('dbo.HistSteps') IS NOT NULL
    DROP FUNCTION dbo.HistSteps;
GO
CREATE FUNCTION dbo.HistSteps(@numsteps AS INT) RETURNS TABLE
AS
RETURN
    SELECT n AS step,
        mn + (n - 1) * stepsize AS lb,
        mn + n * stepsize AS hb
```
FROM dbo.Nums
CROSS JOIN
(SELECT MIN(val) AS mn,
((1E0*MAX(val) + 0.0000000001) - MIN(val))
/ @numsteps AS stepsize
FROM Sales.OrderValues) AS D
WHERE n <= @numsteps;
GO

To test the function, run the following query, which will give you a three-row histogram steps table:

SELECT * FROM dbo.HistSteps(3) AS S;

To return the actual histogram, simply join the steps table and the OrderValues view on the predicate I described earlier (val >= lb AND val < hb), group the data by step number, and return the step number and row count:

SELECT step, COUNT(*) AS numorders
FROM dbo.HistSteps(3) AS S
JOIN Sales.OrderValues AS O
ON val >= lb AND val < hb
GROUP BY step;

This query generates the following histogram:

<table>
<thead>
<tr>
<th>step</th>
<th>numorders</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>803</td>
</tr>
<tr>
<td>2</td>
<td>21</td>
</tr>
<tr>
<td>3</td>
<td>6</td>
</tr>
</tbody>
</table>

You can see that there are 803 small orders, 21 medium orders, and 6 large order. To return a histogram with 10 steps, simply provide 10 as the input to the HistSteps function:

SELECT step, COUNT(*) AS numorders
FROM dbo.HistSteps(10) AS S
JOIN Sales.OrderValues AS O
ON val >= lb AND val < hb
GROUP BY step;

This query generates the following output:

<table>
<thead>
<tr>
<th>step</th>
<th>numorders</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>578</td>
</tr>
<tr>
<td>2</td>
<td>172</td>
</tr>
<tr>
<td>3</td>
<td>46</td>
</tr>
<tr>
<td>4</td>
<td>14</td>
</tr>
<tr>
<td>5</td>
<td>3</td>
</tr>
<tr>
<td>6</td>
<td>6</td>
</tr>
<tr>
<td>7</td>
<td>8</td>
</tr>
<tr>
<td>8</td>
<td>1</td>
</tr>
<tr>
<td>10</td>
<td>2</td>
</tr>
</tbody>
</table>
Note that because you're using an inner join, empty steps are not returned like in the case of step 9. To return empty steps also, you can use the following outer join query:

```sql
SELECT step, COUNT(val) AS numorders
FROM dbo.HistSteps(10) AS S
  LEFT OUTER JOIN Sales.OrderValues AS O
    ON val >= lb AND val < hb
GROUP BY step;
```

As you can see in the output of this query, empty steps are included this time:

<table>
<thead>
<tr>
<th>step</th>
<th>numorders</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>578</td>
</tr>
<tr>
<td>2</td>
<td>172</td>
</tr>
<tr>
<td>3</td>
<td>46</td>
</tr>
<tr>
<td>4</td>
<td>14</td>
</tr>
<tr>
<td>5</td>
<td>3</td>
</tr>
<tr>
<td>6</td>
<td>6</td>
</tr>
<tr>
<td>7</td>
<td>8</td>
</tr>
<tr>
<td>8</td>
<td>1</td>
</tr>
<tr>
<td>9</td>
<td>0</td>
</tr>
<tr>
<td>10</td>
<td>2</td>
</tr>
</tbody>
</table>

**Note** Notice that `COUNT(val)` is used here and not `COUNT(*)`. `COUNT(*)` would incorrectly return 1 for empty steps because the group has an outer row. You have to provide the `COUNT` function an attribute from the nonpreserved side (Orders) to get the correct count.

There's another alternative to taking care of the issue with the step boundaries and the predicate used to identify a match. You can simply check whether the step number is 1, in which case you subtract 1 from the lower bound. Then, in the query generating the actual histogram, you use the predicate `val > lb AND val <= hb`.

Another approach is to check whether the step is the last, and if it is, add 1 to the higher bound. Then use the predicate `val >= lb AND val < hb`.

Here's the revised function implementing the latter approach:

```sql
ALTER FUNCTION dbo.HistSteps(@numsteps AS INT) RETURNS TABLE
AS
RETURN
SELECT n AS step,
    mn + (n - 1) * stepsize AS lb,
    mn + n * stepsize + CASE WHEN n = @numsteps THEN 1 ELSE 0 END AS hb
FROM dbo.Nums
CROSS JOIN
    (SELECT MIN(val) AS mn,
    (1E0*MAX(val) - MIN(val)) / @numsteps AS stepsize
    FROM Sales.OrderValues) AS D
WHERE n <= @numsteps;
GO
And the following query generates the actual histogram:

```sql
SELECT step, COUNT(val) AS numorders
FROM dbo.HistSteps(3) AS S
    LEFT OUTER JOIN Sales.OrderValues AS O
    ON val >= lb AND val < hb
GROUP BY step;
```

### Grouping Factor

In earlier chapters, Chapter 6 in particular, I described a concept called a *grouping factor*. I used it in a problem to isolate islands, or ranges of consecutive elements in a sequence. Recall that the grouping factor is the factor you end up using in your GROUP BY clause to identify the group. In the earlier problem, I demonstrated two techniques to calculate the grouping factor. One method was calculating the maximum value within the group (specifically, the smallest value that is both greater than or equal to the current value and followed by a gap). The other method used row numbers.

Because this chapter covers aggregates, it is appropriate to revisit this very practical problem. In my examples here, I’ll use the Stocks table, which you create and populate by running the following code:

```sql
USE tempdb;

IF OBJECT_ID('Stocks') IS NOT NULL DROP TABLE Stocks;

CREATE TABLE dbo.Stocks
(
    dt    DATE NOT NULL PRIMARY KEY,
    price INT  NOT NULL
);
GO

INSERT INTO dbo.Stocks(dt, price) VALUES
    ('20090801', 13),
    ('20090802', 14),
    ('20090803', 17),
    ('20090804', 40),
    ('20090805', 40),
    ('20090806', 52),
    ('20090807', 56),
    ('20090808', 60),
    ('20090809', 70),
    ('20090810', 30),
    ('20090811', 29),
    ('20090812', 29),
    ('20090813', 40),
    ('20090814', 45),
    ('20090815', 60),
    ('20090816', 60),
```

```sql
```
The Stocks table contains daily stock prices.

**Note** Stock prices are rarely restricted to integers, and there is usually more than one stock, but I'll use integers and a single stock for simplification purposes. Also, stock markets usually don't have activity on Saturdays; because I want to demonstrate a technique over a sequence with no gaps, I introduced rows for Saturdays as well, with the same value that was stored in the preceding Friday.

The request is to isolate consecutive periods where the stock price was greater than or equal to 50. Figure 8-2 has a graphical depiction of the stock prices over time, and the arrows represent the periods you’re supposed to return.

![Stock Values](image.png)

**FIGURE 8-2** Periods in which stock values were greater than or equal to 50
For each such period, you need to return the starting date, ending date, duration in days, and the peak (maximum) price.

Let’s start with a solution that does not use row numbers. The first step here is to filter only the rows where the price is greater than or equal to 50. Unlike the traditional problem where you really have gaps in the data, here the gaps appear only after filtering. The whole sequence still appears in the Stocks table. You can use this fact to your advantage. Of course, you could take the long route of calculating the maximum date within the group (the first date that is both later than or equal to the current date and followed by a gap). However, a much simpler and faster technique to calculate the grouping factor would be to return the first date that is greater than the current, on which the stock’s price is less than 50. Here, you still get the same grouping factor for all elements of the same target group, yet you need only one nesting level of subqueries instead of two.

Here’s the query:

```
SELECT MIN(dt) AS startrange, MAX(dt) AS endrange,
       DATEDIFF(day, MIN(dt), MAX(dt)) + 1 AS numdays,
       MAX(price) AS maxprice
FROM (SELECT dt, price,
       (SELECT MIN(dt)
        FROM dbo.Stocks AS S2
        WHERE S2.dt > S1.dt
        AND price < 50) AS grp
       FROM dbo.Stocks AS S1
       WHERE price >= 50) AS D
GROUP BY grp;
```

This query generates the following output, which is the desired result:

<table>
<thead>
<tr>
<th>startrange</th>
<th>endrange</th>
<th>numdays</th>
<th>maxprice</th>
</tr>
</thead>
<tbody>
<tr>
<td>2009-08-06</td>
<td>2009-08-09</td>
<td>4</td>
<td>70</td>
</tr>
<tr>
<td>2009-08-15</td>
<td>2009-08-19</td>
<td>5</td>
<td>60</td>
</tr>
<tr>
<td>2009-08-25</td>
<td>2009-08-28</td>
<td>4</td>
<td>70</td>
</tr>
</tbody>
</table>

Of course, post filtering, you could consider the problem as a classic islands problem in a temporal sequence scenario and address it with the very efficient technique that uses the ROW_NUMBER function, as I described in Chapter 6:

```
SELECT MIN(dt) AS startrange, MAX(dt) AS endrange,
       DATEDIFF(day, MIN(dt), MAX(dt)) + 1 AS numdays,
       MAX(price) AS maxprice
FROM (SELECT dt, price,
       DATEADD(day, -1 * ROW_NUMBER() OVER(ORDER BY dt), dt) AS grp
       FROM dbo.Stocks AS S1
       WHERE price >= 50) AS D
GROUP BY grp;
```
Grouping Sets

A grouping set is simply a set of attributes that you group by, such as in a query that has the following GROUP BY clause:

```
GROUP BY custid, empid, YEAR(orderdate)
```

You define a single grouping set—`(custid, empid, YEAR(orderdate))`. Traditionally, aggregate queries define a single grouping set, as demonstrated in the previous example. SQL Server supports features that allow you to define multiple grouping sets in the same query and return a single result set with aggregates calculated for the different grouping sets.

The ability to define multiple grouping sets in the same query was available prior to SQL Server 2008 in the form of options called WITH CUBE and WITH ROLLUP and a helper function called GROUPING. However, those options were neither standard nor flexible enough. SQL Server 2008 introduces several new features that allow you to define multiple grouping sets in the same query. The new features include the GROUPING SETS, CUBE, and ROLLUP subclauses of the GROUP BY clause (not to be confused with the older WITH CUBE and WITH ROLLUP options) and the helper function GROUPING_ID. These new features are ISO compliant and substantially more flexible than the older, nonstandard ones.

Before I provide the technicalities of the grouping sets–related features, I’d like to explain the motivation for using those and the kind of problems that they solve. If you’re interested only in the technicalities, feel free to skip this section.

Consider a data warehouse with a large volume of sales data. Users of this data warehouse frequently need to analyze aggregated views of the data by various dimensions, such as customer, employee, product, time, and so on. When a user such as a sales manager starts the analysis process, the user asks for some initial aggregated view of the data—for example, the total quantities for each customer and year. This request translates in more technical terms to a request to aggregate data for the grouping set `(custid, YEAR(orderdate))`. The user then analyzes the data, and based on the findings the user makes the next request—say, to return total quantities for each year and month. This is a request to aggregate data for a new grouping set—`(YEAR(orderdate), MONTH(orderdate))`. In this manner the user keeps asking for different aggregated views of the data—in other words, to aggregate data for different grouping sets.

To address such analysis needs of your system’s users, you could develop an application that generates a different GROUP BY query for each user request. Each query would need to scan all applicable base data and process the aggregates. With large volumes of data, this approach is very inefficient, and the response time will probably be unreasonable.

To provide fast response time, you need to preprocess aggregates for all grouping sets that users might ask for and store those in the data warehouse. For example, you could do this every night. When the user requests aggregates for a certain grouping set, the aggregates will be readily available. The problem is that given $n$ dimensions, $2^n$ possible grouping sets can be constructed from those dimensions. For example, with 10 dimensions you get 1,024 grouping sets. If you actually run a separate GROUP BY query for each, it will take a very long time to process all aggregates, and you might not have a sufficient processing window for this.
This is where the new grouping features come into the picture. They allow you to calculate aggregates for multiple grouping sets without rescanning the base data separately for each. Instead, SQL Server scans the data the minimum number of times that the optimizer figures is optimal, calculates the base aggregates, and on top of the base aggregates calculates the super aggregates (aggregates of aggregates).

Note that the product Microsoft SQL Server Analysis Services (SSAS, or just AS) specializes in preprocessing aggregates for multiple grouping sets and storing them in a specialized multidimensional database. It provides very fast response time to user requests, which are made with a language called Multidimensional Expressions (MDX). The recommended approach to handling needs for dynamic analysis of aggregated data is to implement an Analysis Services solution. However, some organizations don’t need the scale and sophistication levels provided by Analysis Services and would rather get the most they can from their relational data warehouse with T-SQL. For those organizations, the new grouping features provided by SQL Server can come in very handy.

The following sections describe the technicalities of the grouping sets–related features supported by SQL Server 2008.

Sample Data

In my examples I will use the Orders table that you create and populate in tempdb by running the code provided earlier in Listing 8-1. This code is provided here again for your convenience:

```sql
SET NOCOUNT ON;
USE tempdb;
IF OBJECT_ID('dbo.Orders', 'U') IS NOT NULL DROP TABLE dbo.Orders;
GO

CREATE TABLEdbo.Orders
(
    orderid INT NOT NULL,
    orderdate DATETIME NOT NULL,
    empid INT NOT NULL,
    custid VARCHAR(5) NOT NULL,
    qty INT NOT NULL,
    CONSTRAINT PK_Orders PRIMARY KEY(orderid)
);
GO

INSERT INTO dbo.Orders
(orderid, orderdate, empid, custid, qty)
VALUES
(30001, '20060802', 3, 'A', 10),
(10001, '20061224', 1, 'A', 12),
(10005, '20061224', 1, 'B', 20),
(40001, '20070109', 4, 'A', 40),
(10006, '20070118', 1, 'C', 14),
)```
The GROUPING SETS Subclause

SQL Server 2008 allows you to define multiple grouping sets in the same query by using the new GROUPING SETS subclause of the GROUP BY clause. Within the outermost pair of parentheses, you specify a list of grouping sets separated by commas. Each grouping set is expressed by a pair of parentheses containing the set's elements separated by commas. For example, the following query defines four grouping sets:

```
SELECT custid, empid, YEAR(orderdate) AS orderyear, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY GROUPING SETS
(  
  ( custid, empid, YEAR(orderdate) ),
  ( custid, YEAR(orderdate)       ),
  ( empid, YEAR(orderdate)        ),
  ()
);
```

The first grouping set is \((\text{custid}, \text{empid}, \text{YEAR(orderdate)})\), the second is \((\text{custid}, \text{YEAR(orderdate)})\), the third is \((\text{empid}, \text{YEAR(orderdate)})\), and the fourth is the empty grouping set \((\text{})\), which is used to calculate grand totals. This query generates the following output:

<table>
<thead>
<tr>
<th>custid</th>
<th>empid</th>
<th>orderyear</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>2006</td>
<td>12</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>2006</td>
<td>20</td>
</tr>
<tr>
<td>NULL</td>
<td>1</td>
<td>2006</td>
<td>32</td>
</tr>
<tr>
<td>C</td>
<td>1</td>
<td>2007</td>
<td>14</td>
</tr>
<tr>
<td>NULL</td>
<td>1</td>
<td>2007</td>
<td>14</td>
</tr>
<tr>
<td>B</td>
<td>2</td>
<td>2007</td>
<td>12</td>
</tr>
<tr>
<td>NULL</td>
<td>2</td>
<td>2007</td>
<td>12</td>
</tr>
<tr>
<td>C</td>
<td>2</td>
<td>2008</td>
<td>20</td>
</tr>
<tr>
<td>NULL</td>
<td>2</td>
<td>2008</td>
<td>20</td>
</tr>
<tr>
<td>A</td>
<td>3</td>
<td>2006</td>
<td>10</td>
</tr>
<tr>
<td>C</td>
<td>3</td>
<td>2006</td>
<td>22</td>
</tr>
<tr>
<td>D</td>
<td>3</td>
<td>2006</td>
<td>30</td>
</tr>
<tr>
<td>NULL</td>
<td>3</td>
<td>2006</td>
<td>62</td>
</tr>
<tr>
<td>B</td>
<td>3</td>
<td>2008</td>
<td>15</td>
</tr>
<tr>
<td>NULL</td>
<td>3</td>
<td>2008</td>
<td>15</td>
</tr>
<tr>
<td>A</td>
<td>4</td>
<td>2007</td>
<td>40</td>
</tr>
<tr>
<td>NULL</td>
<td>4</td>
<td>2007</td>
<td>40</td>
</tr>
<tr>
<td>A</td>
<td>4</td>
<td>2008</td>
<td>10</td>
</tr>
<tr>
<td>NULL</td>
<td>4</td>
<td>2008</td>
<td>10</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
<td>2005</td>
<td></td>
</tr>
<tr>
<td>A</td>
<td>NULL</td>
<td>2006</td>
<td>22</td>
</tr>
<tr>
<td>B</td>
<td>NULL</td>
<td>2006</td>
<td>20</td>
</tr>
</tbody>
</table>
As you can see in the output of the query, NULLs are used as placeholders in inapplicable attributes. You could also think of these NULLs as indicating that the row represents an aggregate over all values of that column. This way, SQL Server can combine rows associated with different grouping sets to one result set. So, for example, in rows associated with the grouping set \((\text{custid}, \text{YEAR(orderdate)})\), the \text{empid} column is NULL. In rows associated with the empty grouping set, the columns \text{empid}, \text{custid}, and \text{orderyear} are NULLs and so on.

Compared to a query that unifies the result sets of four GROUP BY queries, our query that uses the GROUPING SETS subclause requires much less code. It has a performance advantage as well. Examine the execution plan of this query shown in Figure 8-3.

![Execution plan of query with GROUPING SETS subclause](C08626034.indd)

Observe that even though the query defines four grouping sets, the execution plan shows only two scans of the data. In particular, observe that the first branch of the plan shows two Stream Aggregate operators. The Sort operator sorts the data by \text{empid}, \text{YEAR(orderdate)}, \text{custid}. Based on this sorting, the first Stream Aggregate operator calculates the aggregates for the grouping set \((\text{custid}, \text{empid}, \text{YEAR(orderdate)})\); the second Stream Aggregate operates
on the results of the first and calculates the aggregates for the grouping set \((\text{empid}, \ \text{YEAR(orderdate)})\) and the empty grouping set. The second branch of the plan sorts the data by \(\text{YEAR(orderdate)}\), \(\text{custid}\) to allow the Stream Aggregate operator that follows to calculate aggregates for the grouping set \((\text{custid}, \ \text{YEAR(orderdate)})\).

Following is a query that is logically equivalent to the previous one, except that this one actually invokes four GROUP BY queries—one for each grouping set—and unifies their result sets:

```sql
SELECT custid, empid, YEAR(orderdate) AS orderyear, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY custid, empid, YEAR(orderdate)
UNION ALL
SELECT custid, NULL AS empid, YEAR(orderdate) AS orderyear, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY custid, YEAR(orderdate)
UNION ALL
SELECT NULL AS custid, empid, YEAR(orderdate) AS orderyear, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY empid, YEAR(orderdate)
UNION ALL
SELECT NULL AS custid, NULL AS empid, NULL AS orderyear, SUM(qty) AS qty
FROM dbo.Orders;
```

The execution plan for this query is shown in Figure 8-4. You can see that the data is scanned four times.

![Execution plan of code unifying four GROUP BY queries](image)

SQL Server 2008 allows you to define up to 4,096 grouping sets in a single query.
The CUBE Subclause

SQL Server 2008 also introduces the CUBE subclause of the GROUP BY clause (not to be confused with the older WITH CUBE option). The CUBE subclause is merely an abbreviated way to express a large number of grouping sets without actually listing them in a GROUPING SETS subclause. CUBE accepts a list of elements as input and defines all possible grouping sets out of those, including the empty grouping set. In set theory, this is called the power set of a set. The power set of a set V is the set of all subsets of V. Given n elements, CUBE produces $2^n$ grouping sets. For example, \texttt{CUBE(a, b, c)} is equivalent to \texttt{GROUPING SETS( (a, b, c), (a, b), (a, c), (b, c), (a), (b), (c), () )}.

The following query uses the CUBE option to define all four grouping sets that can be made of the elements \texttt{custid} and \texttt{empid}:

```sql
SELECT custid, empid, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY CUBE(custid, empid);
```

This query generates the following output:

<table>
<thead>
<tr>
<th>custid</th>
<th>empid</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>12</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>20</td>
</tr>
<tr>
<td>C</td>
<td>1</td>
<td>14</td>
</tr>
<tr>
<td>NULL</td>
<td>1</td>
<td>46</td>
</tr>
<tr>
<td>B</td>
<td>2</td>
<td>12</td>
</tr>
<tr>
<td>C</td>
<td>2</td>
<td>20</td>
</tr>
<tr>
<td>NULL</td>
<td>2</td>
<td>32</td>
</tr>
<tr>
<td>A</td>
<td>3</td>
<td>10</td>
</tr>
<tr>
<td>B</td>
<td>3</td>
<td>15</td>
</tr>
<tr>
<td>C</td>
<td>3</td>
<td>22</td>
</tr>
<tr>
<td>D</td>
<td>3</td>
<td>30</td>
</tr>
<tr>
<td>NULL</td>
<td>3</td>
<td>77</td>
</tr>
<tr>
<td>A</td>
<td>4</td>
<td>50</td>
</tr>
<tr>
<td>NULL</td>
<td>4</td>
<td>50</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
<td>205</td>
</tr>
<tr>
<td>A</td>
<td>NULL</td>
<td>72</td>
</tr>
<tr>
<td>B</td>
<td>NULL</td>
<td>47</td>
</tr>
<tr>
<td>C</td>
<td>NULL</td>
<td>56</td>
</tr>
<tr>
<td>D</td>
<td>NULL</td>
<td>30</td>
</tr>
</tbody>
</table>

The following query using the GROUPING SETS subclause is equivalent to the previous query:

```sql
SELECT custid, empid, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY GROUPING SETS

(  
  ( custid, empid ),
  ( custid        ),
  ( empid         ),
  ()
);
```
Note that each of the elements in the list you provide to CUBE as input can be made of either a single attribute or multiple attributes. The previous CUBE expression used two single-attribute elements. To define a multi-attribute element, simply list the element’s attributes in parentheses. As an example, the expression CUBE( \( x, y, z \) ) has three single-attribute elements and defines eight grouping sets: \( (x, y, z), (x, y), (x, z), (y, z), (x), (y), (z), () \). The expression CUBE( \( (x, y), z \) ) has one two-attribute element and one single-attribute element and defines four grouping sets: \( (x, y, z), (x, y), (z), () \).

Prior to SQL Server 2008, you could achieve something similar to what the CUBE subclause gives you by using a WITH CUBE option that you specified after the GROUP BY clause, like so:

```
SELECT custid, empid, SUM(qty) AS qty
FROM dbo.Orders
GROUP BY custid, empid
WITH CUBE;
```

This is an equivalent to our previous CUBE query, but it has two drawbacks. First, it’s not standard, while the new CUBE subclause is. Second, when you specify the WITH CUBE option, you cannot define additional grouping sets beyond the ones defined by CUBE, while you can with the new CUBE subclause.

**The ROLLUP Subclause**

The new ROLLUP subclause of the GROUP BY clause is similar to the CUBE subclause. It also allows defining multiple grouping sets in an abbreviated way. However, while CUBE defines all possible grouping sets that can be made of the input elements (the power set), ROLLUP defines only a subset of those. ROLLUP assumes a hierarchy between the input elements. For example, \( \text{ROLLUP}(a, b, c) \) assumes a hierarchy between the elements \( a, b, \) and \( c \). When there is a hierarchy, not all possible grouping sets that can be made of the input elements make sense in terms of having business value. Consider, for example, the hierarchy country, region, city. You can see the business value in the grouping sets \((\text{country, region, city}), (\text{country, region}), (\text{country}), \) and \((())\). But as grouping sets, \((\text{city}), (\text{region}), (\text{region, city})\) and \((\text{country, city})\) have no business value. For example, the grouping set \((\text{city})\) has no business value because different cities can have the same name, and a business typically needs totals by city, not by city name. When the input elements represent a hierarchy, ROLLUP produces only the grouping sets that make business sense for the hierarchy. Given \( n \) elements, ROLLUP will produce \( n + 1 \) grouping sets.

The following query shows an example of using the ROLLUP subclause:

```
SELECT
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate));
```
Out of the three input elements, ROLLUP defines four (3 + 1) grouping sets—\((\text{YEAR(orderdate)}, \text{MONTH(orderdate)}, \text{DAY(orderdate)})\), \((\text{YEAR(orderdate)}, \text{MONTH(orderdate)})\), \((\text{YEAR(orderdate)})\), and \(()\). This query generates the following output:

<table>
<thead>
<tr>
<th>orderyear</th>
<th>ordermonth</th>
<th>orderday</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>2006</td>
<td>4</td>
<td>18</td>
<td>22</td>
</tr>
<tr>
<td>2006</td>
<td>4</td>
<td>NULL</td>
<td>22</td>
</tr>
<tr>
<td>2006</td>
<td>8</td>
<td>2</td>
<td>10</td>
</tr>
<tr>
<td>2006</td>
<td>8</td>
<td>NULL</td>
<td>10</td>
</tr>
<tr>
<td>2006</td>
<td>9</td>
<td>7</td>
<td>30</td>
</tr>
<tr>
<td>2006</td>
<td>9</td>
<td>NULL</td>
<td>30</td>
</tr>
<tr>
<td>2006</td>
<td>12</td>
<td>24</td>
<td>32</td>
</tr>
<tr>
<td>2006</td>
<td>12</td>
<td>NULL</td>
<td>32</td>
</tr>
<tr>
<td>2006</td>
<td>NULL</td>
<td>NULL</td>
<td>94</td>
</tr>
<tr>
<td>2007</td>
<td>1</td>
<td>9</td>
<td>40</td>
</tr>
<tr>
<td>2007</td>
<td>1</td>
<td>18</td>
<td>14</td>
</tr>
<tr>
<td>2007</td>
<td>1</td>
<td>NULL</td>
<td>54</td>
</tr>
<tr>
<td>2007</td>
<td>2</td>
<td>12</td>
<td>12</td>
</tr>
<tr>
<td>2007</td>
<td>2</td>
<td>NULL</td>
<td>12</td>
</tr>
<tr>
<td>2007</td>
<td>NULL</td>
<td>NULL</td>
<td>66</td>
</tr>
<tr>
<td>2008</td>
<td>2</td>
<td>12</td>
<td>10</td>
</tr>
<tr>
<td>2008</td>
<td>2</td>
<td>16</td>
<td>20</td>
</tr>
<tr>
<td>2008</td>
<td>2</td>
<td>NULL</td>
<td>30</td>
</tr>
<tr>
<td>2008</td>
<td>4</td>
<td>18</td>
<td>15</td>
</tr>
<tr>
<td>2008</td>
<td>4</td>
<td>NULL</td>
<td>15</td>
</tr>
<tr>
<td>2008</td>
<td>NULL</td>
<td>NULL</td>
<td>45</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
<td>205</td>
</tr>
</tbody>
</table>

This query is equivalent to the following query that uses the GROUPING SETS subclause to define the aforementioned grouping sets explicitly:

```sql
SELECT
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
    GROUPING SETS
    (
        ( YEAR(orderdate), MONTH(orderdate), DAY(orderdate) ),
        ( YEAR(orderdate), MONTH(orderdate)               ),
        ( YEAR(orderdate)                                   ),
        ()
    );
```

Like with CUBE, each of the elements in the list you provide to ROLLUP as input can be made of either a single attribute or multiple attributes. As an example, the expression ROLLUP( x, y, z ) defines four grouping sets: \((x, y, z)\), \((x, y)\), \((x)\), and \(()\). The expression ROLLUP( x, y, z ) defines three grouping sets: \((x, y, z)\), \((x, y)\), \((x)\).
Similar to the WITH CUBE option that I described earlier, previous versions of SQL Server prior to SQL Server 2008 supported a WITH ROLLUP option. Following is a query that is equivalent to the previous ROLLUP query, except that it uses the older WITH ROLLUP option:

```sql
SELECT
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
FROM dbo.Orders
GROUP BY YEAR(orderdate), MONTH(orderdate), DAY(orderdate)
WITH ROLLUP;
```

Like the WITH CUBE option, the WITH ROLLUP option is nonstandard and doesn't allow you to define further grouping sets in the same query.

**Grouping Sets Algebra**

One beautiful thing about the design of the grouping sets–related features implemented in SQL Server 2008 is that they support a whole algebra of operations that can help you define a large number of grouping sets using minimal coding. You have support for operations that you can think of as multiplication, division, and addition.

**Multiplication**

Multiplication means producing a Cartesian product of grouping sets. You perform multiplication by separating GROUPING SETS subclauses (or the abbreviated CUBE and ROLLUP subclauses) by commas. For example, if A represents a set of attributes \(a_1, a_2, \ldots, a_n\), and B represents a set of attributes \(b_1, b_2, \ldots, b_n\), and so on, the product \(\text{GROUPING SETS}( (A), (B), (C) ), \text{GROUPING SETS}( (D), (E) )\) is equal to \(\text{GROUPING SETS}( (A, D), (A, E), (B, D), (B, E), (C, D), (C, E) )\).

Consider the following query and try to figure out which grouping sets it defines:

```sql
SELECT custid, empid,
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
    CUBE(custid, empid),
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate));
```

First, expand the CUBE and ROLLUP subclauses to the corresponding GROUPING SETS subclauses, and you get the following query:

```sql
SELECT custid, empid,
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
    CUBE(custid, empid),
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate));
```
FROM dbo.Orders
GROUP BY
  GROUPING SETS
  (
    ( custid, empid ),
    ( custid ),
    ( empid ),
    ()
  ),
GROUPING SETS
  (YEAR(orderdate), MONTH(orderdate), DAY(orderdate)),
  (YEAR(orderdate), MONTH(orderdate)),
  (YEAR(orderdate)),
  ()
);

Now apply the multiplication between the GROUPING SETS subclauses, and you get the following query:

SELECT custid, empid,
  YEAR(orderdate) AS orderyear,
  MONTH(orderdate) AS ordermonth,
  SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
  GROUPING SETS
  (custid, empid, YEAR(orderdate), MONTH(orderdate), DAY(orderdate)),
  (custid, empid, YEAR(orderdate), MONTH(orderdate)),
  (custid, empid, YEAR(orderdate)),
  (custid, empid),
  (custid, YEAR(orderdate), MONTH(orderdate), DAY(orderdate)),
  (custid, YEAR(orderdate), MONTH(orderdate)),
  (custid, YEAR(orderdate)),
  (custid),
  (empid, YEAR(orderdate), MONTH(orderdate), DAY(orderdate)),
  (empid, YEAR(orderdate), MONTH(orderdate)),
  (empid, YEAR(orderdate)),
  (empid),
  (YEAR(orderdate), MONTH(orderdate), DAY(orderdate)),
  (YEAR(orderdate), MONTH(orderdate)),
  (YEAR(orderdate)),
  ()
);

**Division**

When multiple grouping sets in an existing GROUPING SETS subclause share common elements, you can separate the common elements to another GROUPING SETS subclause and multiply the two. The concept is similar to arithmetic division, where you divide operands of an expression by a common element and pull it outside the parentheses. For example, \((5 \times 3 + 5 \times 7)\) can be expressed as \((5) \times (3 + 7)\). Based on this logic, you can sometimes reduce
the amount of code needed to define multiple grouping sets. For example, see if you can reduce the code in the following query while preserving the same grouping sets:

```sql
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
GROUPING SETS
  (
    ( custid, empid, YEAR(orderdate), MONTH(orderdate) ),
    ( custid, empid, YEAR(orderdate) ),
    ( custid, YEAR(orderdate), MONTH(orderdate) ),
    ( custid, YEAR(orderdate) ),
    ( empid, YEAR(orderdate), MONTH(orderdate) ),
    ( empid, YEAR(orderdate) )
  );
```

Because `YEAR(orderdate)` is a common element to all grouping sets, you can move it to another GROUPING SETS subclause and multiply the two, like so:

```sql
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
GROUPING SETS
  (
    ( YEAR(orderdate) ),
  ),
GROUPING SETS
  (
    ( custid, empid, MONTH(orderdate) ),
    ( custid, empid ),
    ( custid, MONTH(orderdate) ),
    ( custid ),
    ( empid, MONTH(orderdate) ),
    ( empid )
  );
```

Note that when a GROUPING SETS subclause contains only one grouping set, it is equivalent to listing the grouping set’s elements directly in the GROUP BY clause. Hence, the previous query is logically equivalent to the following:

```sql
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
```
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
  YEAR(orderdate),
  GROUPING SETS
  (  
    ( custid, empid, MONTH(orderdate) ),
    ( custid, empid      ),
    ( custid,           MONTH(orderdate) ),
    ( custid            ),
    ( empid,           MONTH(orderdate) ),
    ( empid            )
  );

You can reduce this form even further. Notice in the remaining GROUPING SETS subclause that three subsets of elements appear once with \textit{MONTH(orderdate)} and once without. Hence, you can reduce this form to a multiplication between a GROUPING SETS subclause containing those three and another containing two grouping sets, \textit{(MONTH(orderdate))} and the empty grouping set, like so:

\begin{verbatim}
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
  YEAR(orderdate),
  GROUPING SETS
  (  
    ( custid, empid ),
    ( custid      ),
    ( empid      )
  ),
  GROUPING SETS
  (  
    ( MONTH(orderdate) ),
    ()
  );
\end{verbatim}

\textbf{Addition}

Recall that when you separate GROUPING SETS, CUBE, and ROLLUP subclauses by commas, you get a Cartesian product between the sets of grouping sets that each represents. But what if you have an existing GROUPING SETS subclause and you just want to add—not multiply—the grouping sets that are defined by a CUBE or ROLLUP subclause? This can be achieved by specifying the CUBE or ROLLUP subclause (or multiple ones) within the parentheses of the GROUPING SETS subclause.
For example, the following query demonstrates adding the grouping sets defined by a ROLLUP subclause to the grouping sets defined by the hosting GROUPING SETS subclause:

```
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
GROUPING SETS
(
  ( custid, empid ),
  ( custid        ),
  ( empid         ),
  ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate))
);
```

This query is a logical equivalent of the following query:

```
SELECT
custid,
empid,
YEAR(orderdate) AS orderyear,
MONTH(orderdate) AS ordermonth,
SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
GROUPING SETS
(
  ( custid, empid ),
  ( custid        ),
  ( empid         ),
  ( YEAR(orderdate), MONTH(orderdate), DAY(orderdate) ),
  ( YEAR(orderdate), MONTH(orderdate)                        ),
  ( YEAR(orderdate)                                            ),
  ()
);
```

Unfortunately, there is no built-in option to do subtraction. For example, you can't somehow express the idea of CUBE( a, b, c, d ) minus GROUPING SETS ( (a, c), (b, d), () ). Of course, you can achieve this with the EXCEPT set operation and other techniques but not as a direct algebraic operation on grouping sets–related subclauses.

### The GROUPING_ID Function

In your applications you may need to be able to identify the grouping set with which each result row of your query is associated. Relying on the NULL placeholders may lead to convoluted code, not to mention the fact that if a column is defined in the table as allowing NULLs, a NULL in the result will be ambiguous. SQL Server 2008 introduces a very convenient tool for this
purpose in the form of a function called GROUPING_ID. This function accepts a list of attributes as input and constructs an integer bitmap where each bit represents the corresponding attribute (the rightmost bit represents the rightmost input attribute). The bit is 0 when the corresponding attribute is a member of the grouping set and 1 otherwise.

You provide the function with all attributes that participate in any grouping set as input, and you will get a unique integer representing each grouping set. So, for example, the expression GROUPING_ID( a, b, c, d ) would return 0 ( 0×8 + 0×4 + 0×2 + 0×1 ) for rows associated with the grouping set ( a, b, c, d ), 1 ( 0×8 + 0×4 + 0×2 + 1×1 ) for the grouping set ( a, b, c ), 2 ( 0×8 + 0×4 + 1×2 + 0×1 ) for the grouping set ( a, b, d ), 3 ( 0×8 + 0×4 + 1×2 + 1×1 ) for the grouping set ( a, b ), and so on.

The following query demonstrate the use of the GROUPING_ID function:

SELECT
  GROUPING_ID(
    custid, empid, 
    YEAR(orderdate), MONTH(orderdate), DAY(orderdate) ) AS grp_id,
  custid, empid,
  YEAR(orderdate) AS orderyear,
  MONTH(orderdate) AS ordermonth,
  DAY(orderdate) AS orderday,
  SUM(qty) AS qty
FROM dbo.Orders
GROUP BY
  CUBE(custid, empid),
  ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate));

This query generates the following output:

<table>
<thead>
<tr>
<th>grp_id</th>
<th>custid</th>
<th>empid</th>
<th>orderyear</th>
<th>ordermonth</th>
<th>orderday</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>C</td>
<td>3</td>
<td>2006</td>

<td>9</td>
<td>7</td>
<td>30</td>
</tr>
<tr>
<td>16</td>
<td>NULL</td>
<td>3</td>
<td>2006</td>
<td>9</td>
<td>7</td>
<td>30</td>
</tr>
</tbody>
</table>

For example, the grp_id value 25 represents the grouping set ( YEAR(orderdate), MONTH(orderdate) ). These attributes are represented by the second (value 2) and third (value 4) bits. However, remember that the bits representing members that participate in the grouping set are turned off. The bits representing the members that do not participate in the grouping set are turned on. In our case, those are the first (1), fourth (8), and fifth (16) bits representing the attributes DAY(orderdate), empid and custid, respectively. The sum of the values of the bits that are turned on is 1 + 8 + 16 = 25.
The following query helps you see which bits are turned on or off in each integer bitmap generated by the `GROUPING_ID` function with five input elements:

```sql
SELECT
    GROUPING_ID(e, d, c, b, a) as n,
    COALESCE(e, 1) as [16],
    COALESCE(d, 1) as [8],
    COALESCE(c, 1) as [4],
    COALESCE(b, 1) as [2],
    COALESCE(a, 1) as [1]
FROM (VALUES(0, 0, 0, 0, 0)) AS D(a, b, c, d, e)
GROUP BY CUBE (a, b, c, d, e)
ORDER BY n;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>n</th>
<th>16</th>
<th>8</th>
<th>4</th>
<th>2</th>
<th>1</th>
</tr>
</thead>

</tbody>
</table>

Remember—when the bit is off, the corresponding member is part of the grouping set.

As mentioned, the `GROUPING_ID` function was introduced in SQL Server 2008. You could produce a similar integer bitmap prior to SQL Server 2008, but it involved more work. You could use a function called `GROUPING` that accepts a single attribute as input and returns 0 if
the attribute is a member of the grouping set and 1 otherwise. You could construct the integer bitmap by multiplying the GROUPING value of each attribute by a different power of 2 and summing all values. Here's an example of implementing this logic in a query that uses the older WITH CUBE option:

```sql
SELECT
    GROUPING(custid) * 4 +
    GROUPING(empid) * 2 +
    GROUPING(YEAR(orderdate)) * 1 AS grp_id,
    custid, empid, YEAR(orderdate) AS orderyear,
    SUM(qty) AS totalqty
FROM dbo.Orders
GROUP BY custid, empid, YEAR(orderdate)
WITH CUBE;
```

This query generates the following output:

<table>
<thead>
<tr>
<th>grp_id</th>
<th>custid</th>
<th>empid</th>
<th>orderyear</th>
<th>totalqty</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>A</td>
<td>1</td>
<td>2006</td>
<td>12</td>
</tr>
<tr>
<td>0</td>
<td>B</td>
<td>1</td>
<td>2006</td>
<td>20</td>
</tr>
<tr>
<td>4</td>
<td>NULL</td>
<td>1</td>
<td>2006</td>
<td>32</td>
</tr>
<tr>
<td>0</td>
<td>A</td>
<td>3</td>
<td>2006</td>
<td>10</td>
</tr>
<tr>
<td>0</td>
<td>C</td>
<td>3</td>
<td>2006</td>
<td>22</td>
</tr>
<tr>
<td>0</td>
<td>D</td>
<td>3</td>
<td>2006</td>
<td>30</td>
</tr>
<tr>
<td>4</td>
<td>NULL</td>
<td>3</td>
<td>2006</td>
<td>62</td>
</tr>
<tr>
<td>6</td>
<td>NULL</td>
<td>NULL</td>
<td>2006</td>
<td>94</td>
</tr>
<tr>
<td>0</td>
<td>C</td>
<td>1</td>
<td>2007</td>
<td>14</td>
</tr>
<tr>
<td>4</td>
<td>NULL</td>
<td>1</td>
<td>2007</td>
<td>14</td>
</tr>
</tbody>
</table>

Materialize Grouping Sets

Recall that before I started describing the technicalities of the grouping sets–related features, I explained that one of their uses is to preprocess aggregates for multiple grouping sets and store those in the data warehouse for fast retrieval. The following code demonstrates materializing aggregates for multiple grouping sets, including an integer identifier of the grouping set calculated with the GROUPING_ID function in a table called MyGroupingSets:

```sql
USE tempdb;
IF OBJECT_ID('dbo.MyGroupingSets', 'U') IS NOT NULL  DROP TABLE dbo.MyGroupingSets;
GO

SELECT
    GROUPING_ID(custid, empid, YEAR(orderdate), MONTH(orderdate), DAY(orderdate)) AS grp_id,
    custid, empid,
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
INTO dbo.MyGroupingSets
```

```sql
USE tempdb;
IF OBJECT_ID('dbo.MyGroupingSets', 'U') IS NOT NULL  DROP TABLE dbo.MyGroupingSets;
GO

SELECT
    GROUPING_ID(custid, empid, YEAR(orderdate), MONTH(orderdate), DAY(orderdate)) AS grp_id,
    custid, empid,
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
INTO dbo.MyGroupingSets
```
FROM dbo.Orders
GROUP BY
    CUBE(custid, empid),
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate));

CREATE UNIQUE CLUSTERED INDEX idx_cl_grp_id_grp_attributes
    ON dbo.MyGroupingSets(grp_id, custid, empid, orderyear, ordermonth, orderday);

The index created on the table MyGroupingSets is defined on the grp_id column as the first key to allow efficient retrieval of all rows associated with a single grouping set. For example, consider the following query, which asks for all rows associated with the grouping set (custid, YEAR(orderdate), MONTH(orderdate)):

SELECT *
FROM dbo.MyGroupingSets
WHERE grp_id = 9;

This query generates the following output:

<table>
<thead>
<tr>
<th>grp_id</th>
<th>custid</th>
<th>empid</th>
<th>orderyear</th>
<th>ordermonth</th>
<th>orderday</th>
<th>qty</th>
</tr>
</thead>
<tbody>
<tr>
<td>9</td>
<td>A</td>
<td>NULL</td>
<td>2006</td>
<td>8</td>
<td>NULL</td>
<td>10</td>
</tr>
<tr>
<td>9</td>
<td>A</td>
<td>NULL</td>
<td>2006</td>
<td>12</td>
<td>NULL</td>
<td>12</td>
</tr>
<tr>
<td>9</td>
<td>A</td>
<td>NULL</td>
<td>2007</td>
<td>1</td>
<td>NULL</td>
<td>40</td>
</tr>
<tr>
<td>9</td>
<td>A</td>
<td>NULL</td>
<td>2008</td>
<td>2</td>
<td>NULL</td>
<td>10</td>
</tr>
<tr>
<td>9</td>
<td>B</td>
<td>NULL</td>
<td>2006</td>
<td>12</td>
<td>NULL</td>
<td>20</td>
</tr>
<tr>
<td>9</td>
<td>B</td>
<td>NULL</td>
<td>2007</td>
<td>2</td>
<td>NULL</td>
<td>12</td>
</tr>
<tr>
<td>9</td>
<td>B</td>
<td>NULL</td>
<td>2008</td>
<td>4</td>
<td>NULL</td>
<td>15</td>
</tr>
<tr>
<td>9</td>
<td>C</td>
<td>NULL</td>
<td>2006</td>
<td>4</td>
<td>NULL</td>
<td>22</td>
</tr>
<tr>
<td>9</td>
<td>C</td>
<td>NULL</td>
<td>2007</td>
<td>1</td>
<td>NULL</td>
<td>14</td>
</tr>
<tr>
<td>9</td>
<td>C</td>
<td>NULL</td>
<td>2008</td>
<td>2</td>
<td>NULL</td>
<td>20</td>
</tr>
<tr>
<td>9</td>
<td>D</td>
<td>NULL</td>
<td>2006</td>
<td>9</td>
<td>NULL</td>
<td>30</td>
</tr>
</tbody>
</table>

Figure 8-5 shows the plan for this query.

This plan is very efficient. It scans only the rows that are associated with the requested grouping set because they reside in a consecutive section in the leaf of the clustered index.

Provided that you are using aggregates that are additive measures, like SUM, COUNT, and AVG, you can apply incremental updates to the stored aggregates with only the delta of additions since you last processed those aggregates. You can achieve this by using the new MERGE statement that was introduced in SQL Server 2008. Here I’m just going to show the code to demonstrate how this is done. For details about the MERGE statement, please refer to Chapter 10, “Data Modification.”
Run the following code to simulate another day's worth of order activity (April 19, 2008):

```sql
INSERT INTO dbo.Orders
(orderid, orderdate, empid, custid, qty)
VALUES
(50001, '20080419', 1, 'A', 10),
(50002, '20080419', 1, 'B', 30),
(50003, '20080419', 2, 'A', 20),
(50004, '20080419', 2, 'B', 5),
(50005, '20080419', 3, 'A', 15)
```

Then run the following code to incrementally update the stored aggregates with the new day's worth of data:

```sql
WITH LastDay AS
(
  SELECT
    GROUPING_ID(
      custid, empid,
      YEAR(orderdate), MONTH(orderdate), DAY(orderdate) ) AS grp_id,
    custid, empid,
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate) AS orderday,
    SUM(qty) AS qty
  FROM dbo.Orders
  WHERE orderdate = '20080419'
  GROUP BY
    CUBE(custid, empid),
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate))
)
MERGE INTO dbo.MyGroupingSets AS TGT
USING LastDay AS SRC
ON     (TGT.grp_id    = SRC.grp_id)
AND (TGT.orderyear  = SRC.orderyear
  OR (TGT.orderyear IS NULL AND SRC.orderyear IS NULL))
AND (TGT.ordermonth = SRC.ordermonth
  OR (TGT.ordermonth IS NULL AND SRC.ordermonth IS NULL))
AND (TGT.orderday   = SRC.orderday
  OR (TGT.orderday IS NULL AND SRC.orderday IS NULL))
AND (TGT.custid   = SRC.custid
  OR (TGT.custid IS NULL AND SRC.custid IS NULL))
AND (TGT.empid    = SRC.empid
  OR (TGT.empid IS NULL AND SRC.empid IS NULL))
WHEN MATCHED THEN
  UPDATE SET
    TGT.qty += SRC.qty
WHEN NOT MATCHED THEN
  INSERT (grp_id, custid, empid, orderyear, ordermonth, orderday)
  VALUES (SRC.grp_id, SRC.custid, SRC.empid, SRC.orderyear, SRC.ordermonth, SRC.orderday);
```

The code in the CTE LastDay calculates aggregates for the same grouping sets as in the original query but filters only the last day's worth of data. The MERGE statement then increments the quantities of groups that already exist in the target by adding the new quantities and inserts the groups that don't exist in the target.
Sorting

Consider a request to calculate the total quantity aggregate for all grouping sets in the hierarchy order year > order month > order day. You can achieve this, of course, by simply using the ROLLUP subclause. However, a tricky part of the request is that you need to sort the rows in the output in a hierarchical manner, that is, days of a month, followed by the month total, months of a year followed by the yearly total, and finally the grand total. This can be achieved with the help of the GROUPING function as follows:

```sql
SELECT
    YEAR(orderdate) AS orderyear,
    MONTH(orderdate) AS ordermonth,
    DAY(orderdate)   AS orderday,
    SUM(qty)         AS totalqty
FROM dbo.Orders
GROUP BY
    ROLLUP(YEAR(orderdate), MONTH(orderdate), DAY(orderdate))
ORDER BY
    GROUPING(YEAR(orderdate)) , YEAR(orderdate),
    GROUPING(MONTH(orderdate)) , MONTH(orderdate),
    GROUPING(DAY(orderdate))  , DAY(orderdate);
```

Remember that the GROUPING function returns 0 when the element is a member of a grouping set (representing detail) and 1 when the element isn’t (representing an aggregate). Because we want to present detail before aggregates, the GROUPING function is very convenient. We want to first see the detail of years and at the end the grand total. Within the detail of years, we want to sort by year. Within each year, we want to first see the detail of months and then the year total. Within the detail of months, we want to sort by month. Within the month we want to sort by the detail of days and then month total. Within the detail of days, we want to sort by day.

This query generates the following output:

<table>
<thead>
<tr>
<th>orderyear</th>
<th>ordermonth</th>
<th>orderday</th>
<th>totalqty</th>
</tr>
</thead>
<tbody>
<tr>
<td>2006</td>
<td>4</td>
<td>18</td>
<td>22</td>
</tr>
<tr>
<td>2006</td>
<td>4</td>
<td>NULL</td>
<td>22</td>
</tr>
<tr>
<td>2006</td>
<td>8</td>
<td>2</td>
<td>10</td>
</tr>
<tr>
<td>2006</td>
<td>8</td>
<td>NULL</td>
<td>10</td>
</tr>
<tr>
<td>2006</td>
<td>9</td>
<td>7</td>
<td>30</td>
</tr>
<tr>
<td>2006</td>
<td>9</td>
<td>NULL</td>
<td>30</td>
</tr>
<tr>
<td>2006</td>
<td>12</td>
<td>24</td>
<td>32</td>
</tr>
<tr>
<td>2006</td>
<td>12</td>

<td>1</td>
<td>NULL</td>
<td>54</td>
</tr>
<tr>
<td>2007</td>
<td>2</td>
<td>12</td>
<td>12</td>
</tr>
<tr>
<td>2007</td>
<td>2</td>
<td>NULL</td>
<td>12</td>
</tr>
<tr>
<td>2007</td>
<td>NULL</td>
<td>NULL</td>
<td>66</td>
</tr>
</tbody>
</table>
Conclusion

This chapter covered various solutions to data-aggregation problems that reused fundamental querying techniques I introduced earlier in the book. It also introduced new techniques, such as dealing with tiebreakers by using concatenation, calculating a minimum using the MAX function, pivoting, unpivoting, calculating custom aggregates by using specialized techniques, and more. This chapter also covered the new grouping sets features in SQL Server 2008 and showed how you can use those to efficiently address the need for dynamic analysis of aggregates.

As you probably noticed, data-aggregation techniques involve a lot of logical manipulation. If you're looking for ways to improve your logic, you can practice pure logical puzzles, which have a lot in common with querying problems in terms of the thought processes involved. You can find pure logic puzzles in Appendix A.

About the Authors

Itzik Ben-Gan

Itzik Ben-Gan is a mentor and cofounder of Solid Quality Mentors. An SQL Server Microsoft MVP (Most Valuable Professional) since 1999, Itzik has delivered numerous training events around the world focused on T-SQL querying, query tuning, and programming. Itzik is the author of several books about T-SQL. He has written many articles for SQL Server Magazine as well as articles and white papers for MSDN. Itzik’s speaking engagements include Tech Ed, DevWeek, PASS, SQL Server Magazine Connections, various user groups around the world, and Solid Quality Mentors events.

Lubor Kollar

Lubor Kollar is Group Program Manager in Microsoft Corp. He has been working in SQL Server development organization since 1996. Prior to joining Microsoft, he was developing various DB2 engines at IBM. Currently Lubor is leading SQL Server Customer Advisory Team (SQL CAT) working on the most challenging SQL Server deployments around the world. SQL CAT is responsible for maintaining tight connections between the users and creators of new SQL Server releases. Another goal of SQL CAT is to spread the wisdom learned from the most advanced SQL Server deployments. One of the major channels easily accessible to the widest audience is the www.sqlcat.com Web site.

Dejan Sarka

Dejan Sarka focuses on development of database and business intelligence applications. Besides projects, he spends about half of his time on training and mentoring. He is a frequent speaker at some of the most important international conferences, including PASS, TechEd, and SqlDevCon. He is also indispensable at regional Microsoft events—for example, the NT Conference (the biggest Microsoft conference in Central and Eastern Europe). He is the founder of the Slovenian SQL Server and .NET Users Group. Dejan is the main author, coauthor, or guest author of seven books about databases and SQL Server. Dejan also developed two courses for Solid Quality Learning: Data Modeling Essentials and Data Mining with SQL Server 2008.
Steve Kass

Steve Kass holds a Ph.D. in mathematics from the University of Wisconsin, and he is a professor of Mathematics and Computer Science at Drew University, where he has taught since 1988. An SQL Server Microsoft MVP since 2002, he has written for SQL Server Magazine and spoken at SQL Server Magazine Connections events and to user groups in the New York City area. Steve's mathematical work has appeared in Complex Systems and the Journal of Algebra.
